Routine methods of treatment will often prove disappointing. If our treatment is to be successful it must be applied with a full understanding of the conditions present in each case, a knowledge of what can be accomplished, and how it is to be brought about. To this end a history, going fully into the details of the patient's habits and life will be of the utmost assistance. A careful study and examination of the urine is indispensable, not only on the first visit, but at each subsequent one, as the character of the urine is one of the chief guides to treatment.

Rectal examination of the prostate affords us information of the greatest importance. Its size, consistency, and character can be determined by this means. This is to be supplemented by measurement of the internal enlargement of the prostate. The increase in urethral length is our guide in this and is ascertained by the passage of a small, soft rubber catheter. As soon as urine begins to flow the point at the meatus is noted and the measurement of the remainder ascertained. The length of the catheter being known, the urethral length is thus determined. The amount and quantity of the residual urine can now be determined, the patient having previously voided his urine.

The cystoscope may in some cases be of considerable assistance; ordinarily, however, the information obtained from it is not sufficient to compensate for the traumatism to which its use gives rise; the less unnecessary instrumentation in these cases the better. The slightest injury resulting from the passage of instruments may in some cases be the starting point of a very acute cystitis, if it is not already present. The violent inflammatory symptoms to which it gives rise render the patient all the more uncomfortable, and every effort should be made to prevent this complication. The too sudden or complete withdrawal of the urine may also give rise to cystitis, as conditions favoring this

*Read before the City (Charity) Hospital Alumni Association.

complication are generally present and it needs a very slight exciting cause to start an inflammation which is, on account of the conditions present, extremely difficult to cure.

It is, of course, manifestly impossible to alter the character of the prostatic enlargement after interstitial changes have taken place in that organ. Much can be done, however, to prevent it if the patient is seen early, when the glandular strictures are principally involved. At this time the prostate may be only slightly enlarged; it will be soft and boggy on rectal examination and somewhat tender. In other words a catarrhal prostatitis is present and the indications are to free the glands of the accumulation and relieve the congestion in and about the gland. Massage at sufficiently frequent intervals to keep the glands well emptied is to be employed. Hot rectal irrigations are very beneficial in relieving congestion and should be given once or twice a day. While a careful watch should be kept on the urine to see that it does not become irritating.

The patient must be advised as to his habits, and mode of life. Moderate exercise is advisable, but horseback and bicycle riding are to be avoided. Such articles of diet as are irritating to the urethral mucous membranes must not be allowed. All alcoholics must of course be stopped, as it is a well-known fact that they exert a very harmful effect on the urethral mucous membranes, and as the latter are already in a state of congestion or hyperemia every effort must be made to relieve this. The remedy which, in my experience, is most useful in accomplishing this is nitrate of silver. The applications should be made by means of a small soft rubber catheter attached to a small syringe. The solutions should be mild at first and increased or decreased according to the effect produced.

Internal medication depends upon how much irritation is present and the condition of the urine. A highly acid urine with signs of considerable irritation calls for alkalies, in combination with such remedies as uva ursi and triticum repens. When urinary antiseptics are indicated, urotropin (hexamethylenamine) or some similar preparation should be employed.

Residual urine in these cases is not ordinarily present, and although acute retention may occur at any time, it is much more apt to be in the later stages.

Where interstitial changes have taken place in the prostatic tissues and the prostate is hard and firm, massage is contraindicated. The hot rectal irrigations may, however, be employed with great benefit, or the hot sitz bath may be substituted if the rectal irrigations are not well borne.

More or less residual urine will now be present. It is not altogether dependent on the amount of hypertrophy present, for it will be found to diminish in amount as the congestion is relieved by the treatment already indicated. The amount of residual urine should be watched, and catheterization employed when necessary. So long as the urine is clear a moderate amount of residual will do no particular harm, provided the patient is watched and all means employed to prevent infection and cystitis taking place.

Acute retention may sometimes demand our attention. It is usually brought on by exposure to cold or damp weather or by excesses, alcoholic or otherwise. When it does occur, if it cannot be relieved by the catheter, hot sitz baths, or similar means, suprapubic aspiration must be employed.

The use of the catheter by the patient himself requires consideration as to the patient's condition, surroundings, and intelligence. If it is to be employed they should have very definite instructions as to the manner in which it is to be used, and the method of keeping it clean. In cases of this kind the patients may continue to lead a very comfortable life, using the catheter when necessary and seeming to be fairly well satisfied with their condition; so well satisfied indeed that operation will not be considered.

Cystitis, when present, necessitates frequent and copious irrigation of the bladder beginning with mild solutions of boric acid. Some of the solutions containing formaldehyde are also beneficial. Later solutions of silver nitrate may be employed as indicated.

It must be remembered that stone is a frequent accompaniment of prostatic hypertrophy with cystitis. The *x*-ray is a valuable means of diagnosis, though it may occasionally be misleading. I have known it to show no stone when one was known to be present.

Internal antiseptics such as salol boric acid, or urotropin should be administered as indications require, while the general hygiene of the patient should be looked after.

Under the treatment outlined many of these patients can be rendered comfortable and their condition greatly improved. The obstruction to urination will be greatly relieved, with consequent lessening in the amount of residual urine, while the pain and frequency of urination, such annoying symptoms in these cases, can be greatly benefited.

In conclusion, I do not wish to convey the impression that operative measures are never indicated. On the contrary the benefit to be derived from operation in properly selected cases is fully appreciated. The symptoms are due, however, in many of these cases, to other causes besides the enlarged prostate, which are amenable to treatment, and should therefore be corrected before operation is decided upon.

A FACTOR IN PERINEAL LACERATIONS.*

By WILLIAM H. SHIPPS, M.D.,

BORDENTOWN, N. J.

Laceration of the perineum as an accident of labor is of enough importance, and occurs with sufficient frequency, to render its consideration at all times a subject of interest to those engaged in obstetrical work. That it occurs in a large percentage of labors no one will deny who acquaints himself with current literature, or takes the trouble to make visual examination of his patients the invariable rule after the termination of labor.

In a majority of instances, these perineal tears are so slight as to require for their treatment nothing more than strict attention to asepsis. Occasionally however, the injury to the soft parts is of sufficient importance to demand skilled surgical interference for its relief.

Among the causes tending to produce perineal laceration may be mentioned, abnormal development of the fetal head or trunk, disproportion between the size of the fetus and the pelvic outlet, rude or unnecessary manipulation on the part of the medical attendant, rigidity of the perineum, the unskilled use of the forceps, and lastly violent and uncontrolled expulsive efforts of the mother just prior to the birth of the child. As the object of this paper is simply to deal with the last named factor in the

*Read before the Bordentown Medical Club, January 8 1906.

causation of perineal lacerations, consideration of the other causes will purposely be avoided at this time.

Save in a single instance the writer has never had the misfortune to encounter in his immediate practice what is known as a complete laceration of the perineum involving the rectal sphincter, nor what is termed central laceration in which the presenting part forces its way through a breach in the perineum between the rectal and vaginal outlets, also an ugly sequela of labor; but such perineal tears as have been met with, have for the most part been due to uncontrolled expulsive efforts on the part of the mother. Just why the latter should play an important part in the causation of perineal rupture will the more readily be appreciated when we reflect upon the conditions as usually found in the lying-in chamber. Probably hours have already elapsed since labor began, the woman, worn out with her exertions which she believes have been futile, and anxious to bring to a speedy end her sufferings, listens to the promptings of her friends, and often of her physician, to bear down harder, still harder; again and again she responds to the command, and still the end is not. In a spirit of desperation she braces herself for a final effort, and bringing to bear all her reserve forces, strains with all the energy of which she is possessed, the perineum distends more and more until, with little ceremony, the new life bursts its barriers and enters the outside world, bringing momentary relief to the tired mother and attendants, but in its rapid transit not infrequently forcing its way through the torn and lacerated perineum. Too short a time is given for the physiological softening and stretching of the tissues which furnish the frail barrier to the escape of the fetus, hence, as Parvin states, the integrity of the perineum is imperiled, resulting too often in an accident always a source of dread to the patient and annoyance to the physician. Even with the utmost care, it cannot always be avoided, especially in such cases described by Pajot, in which from some peculiarity of structure the perineum is predestined to suffer.

The first and most important step towards prevention, is to secure the woman's cooperation. Let the case be plainly stated to her, so that she clearly understands that the accoucheur depends upon her aid to deliver safely. It is a rule of the writer, when called to the bedside of a woman in labor, after determining the fact that no obstacle to natural delivery exists, to inform her that all is working well, that the pains she is suffering, while seemingly accomplishing little, are gradually and surely preparing the way for the birth of the child, but that there will come a period just prior to delivery, of which timely warning will be given, when she must cease all bearing-down efforts.

At this juncture she is commanded not to bear down, in fact to hold back as it were the effort at expulsion in order to avoid injury to the perineum; or in plainer language to save her from being torn. As all women dread the idea of injuries of this nature, and particularly the thought of operative interference, little difficulty as a rule is experienced in securing the necessary cooperation. When for any reason the patient will not thus aid, anesthesia is a valuable ally. Thus prepared, one has but to wait until the head presses well down upon the perineum and is about to emerge; then with the right hand acting as a guide and a support to the advancing head, the fingers of the left hand, previously well lubricated, are inserted between the presenting part and the perineum. As the head is about to enter the world, the woman is urged to cease all bearing-down efforts. As the head emerges, the chin is allowed to glide over the fingers of the left hand, the perineum meanwhile being gently pressed backward. The head enters the world with little difficulty, the integrity of the perineum remaining intact in proportion as control over the last expulsive efforts of the woman is secured.

Immediately after the placenta is expelled careful examination of the perineum is made. If in spite of the care exercised I detect a rupture, the necessary stitches are at once introduced, and I hold it good practice to operate in every case of laceration except the most superficial. This I do for the sake of possible good to the patient and for my own protection. Women are ever ready to attribute any future indisposition or physical shortcomings to something done or left undone at a previous labor; and especially is this the case if the thought is suggested by some jealous rival, who, taking advantage of the opportunity and knowing the credulity of his patient, seizes upon the occasion to damn his colleague. Therefore, I say, operate whenever there is the slightest excuse for so doing. I am satisfied, however, that in proportion as we come to recognize the importance of bringing under control the violence of the expulsive efforts in the final act of parturition, will we reduce to a minimum our cases of perineal rupture.

Ocular Injuries.—Melville Black declares that a comparatively slight injury to the eye may, if neglected, result in the loss of the function of this organ. On the other hand, a very serious injury may be so treated at the beginning as to cause but slight impairment of vision. In many cases the physician can greatly assist the oculist by giving a full account of the injury and an accurate description of the appearance of the eye shortly after the injury. Aseptic precautions are a necessity in every wound of the eye. All of the adjacent parts should be carefully cleansed. Unless they are infected, simple incised wounds and scratches of the cornea should not be interfered with except to smooth out misplaced flaps. In order to avoid infection not only must the outside of the lids and lashes be made clean, but they must be kept clean until the wound has healed. The eye should be closed with a dry or moist bichloride dressing. If the eye is very painful, the dressing may be removed and iced cloths applied until pain ceases. Then the local cloths may be continued or the dressing may be replaced. The writer emphasizes the importance of using iced cloths for the prevention of ocular infection. Oil is the one thing to use in a burned eye. The writer prefers castor oil. In serious penetrating wounds of the eyeball every endeavor should be made to combat infection. The writer believes that this is best accomplished by the constant application of iced cloths. If there is any question about the eye containing a foreign body, an *x*-ray picture should be taken by an expert. The foreign body should be removed as soon as possible. Atropine is strongly indicated both in penetrating wounds of the globe and in infected simple wounds. The writer concludes by saying that cocaine is not a remedy. It is a local anesthetic. It serves no good purpose and may do a great deal of harm. —*Colorado Medicine.*

The Pathology of Catarrhal Jaundice.—Sacquépée and Fras have for two years been studying this subject. They have carefully observed the feces in these cases, and they conclude that there does exist a catarrhal jaundice of typhoid type. Catarrhal jaundice can be caused by paratyphoid bacilli of two types, more often by the type called A than by that called B. In more than one-fourth of the cases, the colon bacillus is the cause. In all probability it is true that the typhoid bacillus is equally capable of exciting jaundice. For the present, however, we are not able to determine exactly the extent of its pathogenic function. In certain cases the intimate nature of the disease escapes us completely.—*Le Bulletin Médical,* January 6, 1906.

MEDICAL RECORD.

New York, February 17, 1906.

SEASICKNESS.

WHILE seasickness is, under ordinary conditions, hardly to be classed with the graver maladies, the fact that its relief is still beyond the power of the therapeutist is certainly a reproach to medical science. In spite of all endeavors in this direction, a certain prophylactic, or remedy, seems as hard to get hold of as the philosopher's stone, though no doubt many a sufferer, while prostrate from Neptune's wrath, would be willing to barter that fabled reagent if he had it for a sufficiency of some yet undiscovered Gileadean balm which should restore tranquillity to his perturbed interior. The number of alleged specifics is legion, but though the underlying principle may seem plausible enough on shore, when put to the actual test they are usually a reed to lean upon. To leave aside entirely the host of medicamentous agents, mostly narcotics, that have been recommended, the number of physical remedies suggested is appalling and involves treatment directed toward nearly all the bodily functions. Some authors recommend the application of broad, closely fitting abdominal binders of flannel; others say that tight waistbands must especially be eschewed; some counsel exercise, others quiet; some would have the sufferer refrain from all nourishment, liquid or solid, others bid him, undismayed by each fresh cataclysm, to reship a new and copious cargo of victuals as soon as the last has been discharged. Recognizing the importance of ocular reflexes, some counselors urge susceptible seafarers not to let their gaze rest on the restless waves, others seek safety in spectacles of red glass, and still others paralyze the accommodation of one eye with atropine, or cover it with a bandage, in order to lessen the apparent motion of objects on shipboard. Recently one enthusiastic inventor prophesied great things for a special cot suspended at the four corners from wires running over pulleys and controlled by electric motors in such a way that the mattress was always maintained in the horizontal plane. To add the last touch of sybaritic luxury, the sufferer had only to extend a finger and touch a button when soft zephyrs from an electric fan forming part of the machinery would blow gently across his delighted features.

The latest of these mechanical devices for transmuting queasy landlubbers into storm-proof seadogs consists in a vibrating chair, of which the seat is set in commotion by an electric motor. The idea, apparently, is to distract the victim's attention by the violent agitation of his body to such a degree that the pitching of the vessel will pass unnoticed. This appliance has been made the subject of investigation by Dr. Peters, surgeon of one of the large transatlantic passenger steamers which was provided with six of the chairs, and in a contribution to the *Deutsche medizinische Wochenschrift* of December 14, 1905, he expresses himself as encouraged to continue his observations with the method. It appears that the effect of the vibration is distinctly sedative and produces a marked decrease in the usually abnormally high pulse rate. The beneficial effect in most cases ceased, however, as soon as the patient had left the chair, and it would hardly seem wise to subject anyone to this more or less violent jouncing for an indefinite period of time.

Even should this treatment prove to be efficacious and free from contraindications, it would always be open to the drawback of being accessible only to a small fraction of the large number of passengers to be found on the modern liners, and a method not open to this objection would be preferable. Such a one is that proposed and apparently well tested by Eugene Wolf, which is described in the *Deutsche medizinische Wochenschrift* for January 18, 1906. Wolf bases his procedure on the theory that seasickness is accompanied by great cerebral anemia, and he endeavors to counteract this by the application of very hot compresses to the head. He insists that when carried out according to his directions, the treatment invariably produces good results; and to substantiate his claim, he challenges the advocates of the vibration chair to a contest in which the disciples of whichever method proves least effective in entirely preventing seasickness among a specified number of transatlantic passengers shall pay to a seamen's benevolent association the sum of one thousand marks. Wolf has already published his method in the lay press of Germany, and we here give the essential features of the procedure. The remedy is said to be infallible only if the patient, during its application, refrains from all other attempts at treatment, and does not take food or drink or indulge in smoking. When the first symptoms are felt the patient should lie down perfectly flat as soon as possible. All tight garments should be loosened, and especially constriction by the corset must be avoided. The appliances required consist of a bowl of hot water and two towels. The water must have a temperature of at least 80° C. (176° F.). A towel folded to the width of the forehead is dipped in the hot water, wrung out, and tied tightly about the forehead just as hot as it can possibly be borne. Any available object, such as a buttonhook, toothbrush, shoehorn, etc., is used as a lever to twist it very tightly about the head. The application is at first rather trying, but the process is continued, a second similar towel being promptly substituted for the first, until the patient experiences a sensation of wellbeing over the entire body. The application of the compresses is continued for some time longer, but the sensation of wellbeing usually manifests itself in from one-half to one hour. The onset of thirst gives evidence that the seasickness has been conquered, but the patient must remain recumbent, and take no food until he is really hungry. When this occurs, some toast and a little hot, unsweetened, weak tea, without milk, may be taken, and two hours later the patient may resume his place at the table. The treatment is thorough, and, if followed at the beginning, is said to insure freedom from sickness during the rest of the voyage. The

fact that no special apparatus is required certainly renders this method superior to the vibrating chair, and also to an innovation suggested by Kappmeier. This author applies the same principle by using a sort of cap containing a wet compress which is heated by electricity and is provided with means for securing the requisite tension. In this way, through the action of the heat and pressure, the cranial circulation is improved and an even distribution of the blood throughout the body is secured.

THE LOCAL EFFECTS OF PERITONEAL DRAINAGE.

There is probably no one detail of abdominal surgery which has met with so much interest and attention as the subject of drainage. Hailed at first as a means of deliverance from the high mortality which attended the operation of laparotomy, its employment has constituted a matter for discussion, often prolonged and bitter, until at the present day we find it greatly restricted. And the discussion is yet by no means closed, for, although our knowledge of the subject has been greatly increased by clinical experience, much confusion still exists as to the nature of the reaction of the peritoneum to drainage. It must also be acknowledged that the dangers attending the use of a drain in the abdomen, both immediate and remote, are considerable, and yet the feeling is prevalent among surgeons that the procedure cannot be entirely abandoned. Perhaps the most incontrovertible argument against general peritoneal drainage is an array of facts, based on clinical experience, which show that the general peritoneal cavity cannot be drained by the methods usually advocated. It has been proved to be a physiological and physical impossibility, because drains are almost immediately functionally incapacitated by the formation of an encapsulating sheath of fibrinous exudate and adhesions. J. L. Yates (*Surgery, Gynecology, and Obstetrics*, December, 1905) has gone a step further and has shown by animal experiments that no matter what form of drainage is used, there even results a backward flow from the newly-formed into the general cavity. A number of other points in connection with his studies are also of interest. He asserts that the discharge from the drain and the excess of intraperitoneal fluid is a serous exudate, the result of a mechanical irritation of the peritoneum contiguous to the drain and comes only to an insignificant extent from the general peritoneal cavity. This exudation continues only until the fibrinous material has accomplished encapsulation of the drain by the formation of adhesions. There is no appreciable difference between smooth drains and rough drains as regards the process of encapsulation, the advantage of the former consisting merely in their easy and less painful withdrawal. These assertions practically mean that extraperitoneal drainage alone is possible. But, as the writer truly states, there is little comparison between the peritoneum of a healthy dog and that of a sick man, and principles derived from such sources must be regarded with conservatism. There is, however, a well-established relationship between the experimental results and those of a clinical character, and for this reason it does not seem inopportune to adopt them in part if not as a whole.

Admitting, then, the futility of attempting drainage of the general peritoneal cavity, as well as its possible injurious effects, it remains to be seen how we can best employ localized drainage. It is quite evident that the best results will attend the rapid isolation of the affected area, and this should be accomplished with the least injury to the peritoneum and the least restriction to the normal functions of the viscera and to the early and complete restitution of the abdominal conditions. The drainage material should therefore come in contact only with the surface to be drained, and in passing out of the abdominal cavity should come into relation with the least possible extent of serous surface, and then only with that least likely to be functionally affected. In order to carry out the latter requirement, Yates suggests that, whenever practical, the drain be placed between the omentum and the parietes. In addition, everything must be done to promote abdominal quiet for at least twelve hours, in order to favor the formation of encapsulating adhesions. At the end of twenty-four hours, the core of the drain, which should be constructed on the Mikulicz tampon principle, may be withdrawn, and then the remainder as soon after as the conditions indicate.

These experiments emphasize a belief which is gaining many adherents, that any foreign body placed in the abdominal cavity in the presence of an infection is prejudicial to peritoneal resistance, and we must learn to depend on the latter more than on any mechanical means to overcome inflammatory processes, known ordinarily as peritonitis. When there is nothing to be gained by making an infectious area extraperitoneal, or when the path of a drain cannot be made to afford a passage of least resistance leading outside the body, there does not seem to be, judging from Yates' experiments, any justification for its use, aside from hemostasis.

THE PHYSICIAN'S INCOME.

The medical orator, speaking before congresses of his confrères or in general assemblies, is wont to wax eloquent over the altruistic nature of the practice of medicine, and in warming to his theme he often, especially if he has himself reached that happy state where the ring of the doorbell awakens no thrill, warns his hearers against the evil of "commercialism" in medicine. In daily life he takes his fee of $50 for a consultation, or $500 or more for an operation, with no thought other than that it is his just due, but he deprecates the innocent arts of his poorer brother in winning patients whose $2 fees are needed to pay the butcher or buy shoes for the children. For such as he poor times and prosperous times have no terrors. His clientèle is of the well-to-do, who may, perhaps, have to cut off a few of their luxuries in times of stringency, but who always have enough to pay for health and life. For the ordinary practitioner the problem is very different. He suffers in good times and in bad. In poor seasons his patients are out of work and the doctor's fee looms big, the dispensaries are open, and with a little gulp of pride they go to them for free advice. In times of prosperity they go to the physician's office and pay his fee. But the fee they pay is the

same fee they always paid. The doctor, however, must pay for his necessities the higher prices which general prosperity entails. The butcher charges two or three cents more per pound for meat, milk is a cent or two more a quart, a dollar or two is added to the cost of the children's clothes, the plumber adds 10 per cent. to his little bill, and so on all along the line. But the doctor's fees are still the same. The country's prosperity is his ruin.

This is a serious problem for the physician, as well as for all those in salaried positions, or who live on fixed incomes, and its solution is most difficult. The monetary system in this country adds to the difficulty. In Europe, where the unit is the shilling, or the mark, or the franc, an increase in the professional fee of the poorer doctor may be accomplished by adding a unit, making it five shillings, or marks, insteads of four, or six francs instead of five, but here the unit is a dollar, and an increase of the usual fee by such an amount would be stoutly resisted, and would entail a material loss of patients for one who ventured to insist upon it. There are only two solutions of this problem. One is to restrict the number of physicians—an apparently impossible thing. The standard of requirements for the medical candidate has been very materially raised in the last decade, but the number of medical students has not been appreciably reduced. The only other solution is in concerted action on the part of the profession in any one locality to raise the fees for medical consultation and for operations. But this, if it were practicable, would open the door to the vicious principle of coercion, the dragging down of all to the level of the least efficient, which is the fatal objection to trades unionism. There would always be some who would refuse to adhere to the official fee, and who would then get the patients who could not or would not pay the price demanded by the majority of physicians. The boycott would be the only weapon in such a case, and that would have no terrors for the cut-rate doctor any more than it has now for the quack.

The only salvation for the medical practitioner is so to perfect himself in the art and practice of his profession as to compel patients who value their health and their life to come to him and pay the larger fees which his services are worth. The beginner must struggle along as best he may with a clientèle accustomed to small fees. Gradually, if he is worthy of his profession, he will prove himself, and as he does so he can raise his fees to a living figure. He may lose some patients, but will gain others higher in the social and financial scale, and through application and the exercise of tact may eventually lift himself to the level of the orator who can afford to decry commercialism in medicine.

The Practice of Medicine.

We quoted the other week a definition of medical practice—or, rather, a statement of what was not medical practice—formulated by Justice Deuel of this city. In another court, a few days later, Judge Joseph I. Green suggested another definition, which is much more comprehensive—we fear a little too comprehensive to be generally accepted. "The practice of medicine," he said, "is the exercise or performance of any act, by or through the use of any thing or matter, or by things done, given, or applied, whether with or without the use of drugs or medicine, and whether with or without fee therefor, by a person holding himself or herself out as able to cure disease, with a view to relieve, heal, or cure, and having for its object the prevention, healing, remedying, cure, or alleviation of disease." This definition certainly covers the ground, but it errs on the side of inclusiveness almost as much as the other did on the side of exclusiveness. If this were the legal definition of medical practice, incorporated in the statutes, a well-meaning friend who suggested a hot toddy as good for a cold in the head would be in danger of the judgment. The only saving clause is that which refers to a "person holding himself or herself out as able to cure disease"; but even that would hardly avail, for it is the amateur who claims ability to cure, while the real physician only promises to do what he can to relieve. The practice of medicine is as difficult to define as the practice of law. Everybody knows intuitively what it is, but no one has yet succeeded in formulating a perfectly satisfactory definition of it. Merely as a contribution to the discussion, and recognizing fully its incompleteness, we would offer the following definition as more nearly meeting the requirements than either of those suggested by the two learned jurists: "The practice of medicine is the prescribing of any remedy, material or immaterial, for external or internal use, mental suggestion, the manipulation of any part of the human body, the application of apparatus or mechanical appliances, the prescription of special exercises, or the formulation of rules of diet or hygiene, to be applied in an individual case to the cure or alleviation of disease by one claiming or credited with an ability—either a natural gift or acquired by special training or experience, or in any other way—to cure or relieve any defect or disease of body or mind, and who essays thus to treat a person, not a member of his or her family, whether for a fee paid or expected or without reward of any kind. This does not include the masseur or masseuse, instructor in gymnastics, instrument maker, pharmacist, nurse, or other person applying any therapeutic measure under the direction of a legally qualified physician." Such a definition would not affect sanitary engineers, hygienists, or others who formulate or put in practice measures of diet, hygiene, or sanitation designed to preserve or promote the health of mankind in general, nor would it put a penalty on domestic medicine—occasionally harmful, but impossible to abolish; but it would place restrictions upon quackery and check the activities of those who venture to treat the sick for gain without possessing the necessary qualifications.

Heart Disease and Pregnancy.

A great diversity of opinion exists as to the significance of heart disease in pregnancy. Some hold that this complication is one of extreme gravity, others that it is of comparatively slight importance and may be readily controlled by timely and appropriate treatment. A certain knowledge of the possible ill-effects of this condition has also spread among the laity, and anxious inquiries regarding the outcome are usually addressed to the attending physician by the family and friends. It is often a difficult matter to render a prognosis in any given case, and the uncertainty which exists with respect to this question may, perhaps, be traced to the fact that most observers have failed to recognize any distinction between the various forms of cardiac lesions in their relation to the pregnant state. The importance of this is shown in a lecture by Tuszkai of Budapest, recently published in "Volkmann's Sammlung Klinischer Vorträge,"

No. 407. From a study of the literature and personal observations he is led to propose a grouping of these cases with reference to the prognosis as follows: In the first group may be included those cases in which the cardiac lesion was present before the woman became pregnant. Here the prognosis is in general very bad. In the second group may be gathered those cases in which the disease of the heart, previously in a latent state, has been awakened to activity by the pregnancy. Women suffering from an angiosclerosis or those who have been afflicted with any of the infectious diseases shortly before the pregnancy began, are particularly liable to the complication noted. The diagnosis in these cases will be simplified by a knowledge of such a previous disease and the fact that the cardiac symptoms developed only during the latter months of pregnancy. The prognosis in this class of cases depends entirely on the severity and character of the original disease, being either very good or very bad. In the third group may be included those cases which present cardiac lesions peculiar to pregnancy. If the other two classes can be excluded, the diagnosis is not difficult. In this class belong the slighter forms of heart trouble, which are essentially of a functional character, and therefore furnish a favorable prognosis, the disease usually subsiding promptly after delivery.

News of the Week.

Fifteenth International Medical Congress.—The following addresses will be delivered at the general sessions, April 20 to 25, at Lisbon: (1) Sir Patrick Manson of London, subject not announced; (2) Professor Brissaud of Paris, Infantilism; (3) Dr. José Maria Esquerdo of Madrid subject not announced; (4) Dr. P. Aaser of Christiania, The Relation Between the Acute Infectious Diseases and Tuberculosis; (5) Professor A. A. de Azevedo Sodré of Rio de Janeiro, Pathology in Tropical Countries; (6) Professor Neumann of Vienna. The Anatomical Causes of Relapses in Syphilis and the Methods of Combating Them; (7) Professor Prince Jean Tarchanoff of St. Petersburg, Radium in Biology and Medicine or the Organotherapy of To-Day; (8) Professor Reclus of Paris, Local Anesthetics; (9) Professor von Bergmann of Berlin, The Problems of Modern Surgery.

To Remove Tax from Grain Alcohol.—Hearings are being held by the House Committee on Ways and Means at Washington on several bills to remove the internal revenue tax on grain alcohol for industrial purposes. A strong effort is being made by the painters to secure legislation to this effect in order that it may become unnecessary to use wood alcohol, and an artisan who had lost his eyesight from this cause in refinishing chairs appeared before the committee in support of the measure.

Death from Wood Alcohol.—One man was fatally poisoned, another almost died, and a number of others were made seriously ill as a result of a wood alcohol spree recently held by the prisoners confined in one of the large cells of Castle William, the military prison on Governor's Island. It is supposed that the liquor was smuggled in to the men by the visitors.

Immunization of Cattle Against Tuberculosis.—Von Behring, in a lecture delivered on February 8 before the German Agricultural Council, reasserted his determination not to reveal the details of his tuberculosis treatment for human beings until autumn. He reiterated his well-known views in regard to human and bovine tuberculosis, and said among others things that he was compelled to rely on the results of bovo-vaccination for elaboration of his treatment of human beings. He also described the present status of his method of immunizing cattle by means of a substance which he calls tuberculase, which is now obtainable in stable form. It must be injected subcutaneously, at periods varying from a fortnight to a month. The injection does not require technical skill or veterinary experience. The cost is moderate enough to enable it to be used in ordinary agricultural practice. While deprecating as yet the assumption that tuberculase can be used in treating human consumption, Professor Behring said that the results of his experiments opened a hopeful perspective respecting its employment for this purpose, but he emphasized the statement that as yet there was no scientific basis for assuming it could be so used. He added that he took great pleasure in announcing that he was approaching the aim toward which he had long been working—that is, the production of milk for infants, the use of which would be perfectly free from all danger.

Insanitary Street Cars.—The Manhattan Borough President has threatened to begin proceedings for the annulment of the charters of several of the street car lines operating in the lower east side if the cars are not kept in better order. He says in his letter of warning to the officials that the condition of the cars is positively indecent, that they reek with filth, have probably not received a coat of paint in years, and are in such a dilapidated condition generally as to be a menace to life and limb, as their unclean condition undoubtedly renders them a positive menace to the health of all who are compelled to use them.

Joseph Leidy Memorial.—The sum of $8,000 has been collected for the erection of a statue of the late Dr. Joseph Leidy, at one time president of the Academy of Natural Sciences, Professor of Human and Comparative Anatomy and Zoology in the University of Pennsylvania, and President of the Wagner Free Institute of Science, to be presented to the city of Philadelphia in recognition of his memorable contributions to the natural sciences. Dr. Leidy was born in Philadelphia in 1823 and he died in 1891. It is proposed that $10,000 be raised for the purpose in view.

Cost of the Yellow Fever Outbreak in Mississippi.—A supplemental report of the State Board of Health giving an account of the yellow fever outbreak in Mississippi, last summer, has been submitted to the legislature and shows that the total expenditures made by the board on account of the fever were $43,220.08, the greater portion of which was paid to quarantine guards. The report shows that the fever appeared at fifteen places in the State, and the recapitulation gives 837 cases and 61 deaths.

The Regulation of Marriage.—A bill has been introduced before the legislature at Albany prohibiting the marriage of imbecile, epileptic, insane, or feeble-minded persons; making it a felony for sound-minded persons to marry or live in the marital state with feeble-minded, insane, or epileptic persons or to assist such a marriage; and establishing by appointment by the Governor a commission to investigate the condition of the blind and compile a register thereof.

The Brain of a Thief.—In accordance with his desire, expressed two days before his death, the brain of a noted burglar who died recently in Jefferson Hospital will be turned over to the Wistar Institute for scientific study, and his body will go

to Jefferson Hospital for anatomical purposes. The dead man, who had spent more than one-half of his sixty-five years in jail, is stated to have been of a respectable family and well educated. He always asserted that he was a burglar not of his own free will, but impelled by an irresistible tendency, and he believed that a study of his brain might throw some light on the nature of his mental defect.

Sheltering Guardian Home.—Plans for the erection of a new home for the Hebrew Sheltering Guardian Society to cost $650,000 were announced at the annual meeting of the Board of Directors held February 4 at the institution, One Hundred and Fiftieth Street and Broadway. It is planned to purchase a tract of land of 400 or 500 acres within easy reach of the city and build on it forty or more cottages, each capable of housing twenty-five children. A school house, superintendent's cottage, reception house, and hospital would also be provided. It is expected that many of these cottages, which will cost about $10,000 each, will be donated by families in memory of deceased relatives, for whom the cottages would then be named as a memorial. The building fund now available amounts to about $325,000. A committee has been appointed to select a site, and as soon as this has been secured work will be begun.

Medical College at Pekin.—On February 13 the opening ceremonies of the Union Medical College at Pekin were held, under the auspices of prominent native and foreign dignitaries. The college was established by five Protestant missions acting jointly. Sir Ernest Satow, British Minister to China, presided. President Na Tung of the Board of Foreign Affairs represented the Chinese Imperial Government.

New Health Department Buildings.—The new laboratory building and the remodeled Willard Parker Hospital, at the foot of East Sixteenth Street, were formally opened February 9 by Health Commissioner Darlington, and the buildings were inspected by many physicians, surgeons, bacteriologists, and others interested in medical work.

Vaccination Revolts.—The people living in the neighborhood of York, Pa., are in a thoroughly aroused state owing to the enforcing of the compulsory vaccination act in that county. Threats are made to burn school houses, whip teachers, and punish school directors for insisting that the provisions of the law be carried out. The most disrupted school system is in Springettsbury township, where there are not enough pupils in attendance to fill one schoolhouse. Out of 370 pupils the number has been reduced to ninety-four.

Clean Money.—A bill has been introduced at Washington enabling any person or corporation to send worn out or mutilated United States currency to the Treasurer of the United States by registered mail and to receive in exchange therefor new United States currency without postage or registration charge either way.

Absinthe.—A national petition is being started in France by the trades unions, aided by the leading deputies, of the Left to prohibit the manufacture and sale of absinthe. The petitioners point out that absinthe kills tens of thousands of people annually. More of it is consumed in France than in the rest of the world put together, and it is alleged that it causes epilepsy, tuberculosis, insanity, and crime.

New Hanover County (N. C.) Medical Society.—At the meeting of this society, held on January 29, the following officers were elected for the ensuing year. *President*, Dr. Pride J. Thomas; *Vice-President*, Dr. S. E. Koonce; *Secretary and Treasurer*, Dr. R. H. Bellamy.

The Centennial Celebration of the New York County Medical Society.—The Medical Society of the County of New York will celebrate the one hundredth anniversary of its foundation by a dinner at the Hotel Astor, April 4, 1906. The price of tickets will be $6.00. Further information may be had from any of the committee on arrangements, Drs. W. L. Carr, *Chairman*, 68 West Fifty-first Street; H. S. Stearns, 45 West Fifty-eighth Street; and J. S. Thatcher, 820 Madison Avenue.

Smallpox in a Prison.—A convict in the Western Penitentiary of Pennsylvania who had been imprisoned for over a year has in some manner become infected with smallpox. Every precaution is being taken by the authorities to prevent a spread of the disease among the 950 inmates of the prison, who have all been vaccinated.

The United States Civil Service Commission announces an examination on March 21–22, 1906, to secure eligibles from which to make certification to fill vacancies as they may occur in the position of copyist (male), at $900 per annum, in the Bureau of Pensions. Age limit, twenty to thirty-five years, on the date of the examination. Only male graduates of recognized medical schools may be examined. Applicants should at once apply to the United States Civil Service Commission, Washington, D. C., for application Form 1312. No application will be accepted unless properly executed and filed with the Commission at Washington.

The Thirty-fifth Congress of the German Surgical Society will be held in Berlin April 4 to 7, in order not to conflict with the International Medical Congress to be held in Lisbon. The subjects for special discussion before the congress for this year are as follows: Military Surgery as Exemplified in the Russo-Japanese War; The Surgical Treatment of Ulcer of the Stomach; The Modern Operations for Cancer of the Rectum; Bier's Congestion Treatment in Acute Inflammation.

The Twenty-Third German Congress for Internal Medicine will be held in Munich April 23 to 26, 1906, with Professor v. Strümpell of Breslau in the chair. The pathology of the thyroid gland will be discussed on the first day of the congress by Professor Friedrich Krauss of Berlin and Professor Kocher of Bern.

Monongahela Valley (Pa.) Medical Society.—On January 26 an association with this name was formed by the physicians living in the neighborhood of Monessen. The officers elected for the new organization are: *President*, Dr. Gordon, Bellevernon; *Vice-President*, Dr. H. J. Repman, Charleroi; *Secretary*, Dr. J. W. Hunter, Monessen; *Corresponding Secretary*, Dr. J. C. Enos, Charleroi; *Treasurer*, H. W. Day, Monessen.

Dr. Clara Marshall, for thirty years Professor of Materia Medica and Therapeutics in the Woman's Medical College of Pennsylvania, has resigned from the faculty of that institution.

Obituary Notes.—Dr. Richard A. Terhune of Passaic, N. J., died on February 5, at the age of seventy-seven years. He was graduated in 1850 from the College of Physicians and Surgeons in New York City, and from that time practiced in Passaic until about ten years ago, when he retired from active professional work. He was the third physician of his family, which had practised in Passaic for eighty-five years continuously. Dr.

Terhune was the first mayor of the city. His death was caused by carcinoma of the stomach.

Dr. William E. Swan of New York died on February 4, after a long illness. He received his medical diploma from the College of Physicians and Surgeons in New York City, and after spending some time in Baltimore and Saratoga came to New York two years ago. Dr. Swan was born in Saratoga thirty-nine years ago.

Dr. D. Haven Starr, house physician of the Washington Asylum Hospital, died in that city on February 3, of septicemia, contracted from a patient. He was twenty-seven years of age and had recently finished a period of service at the Lying-in Hospital, New York.

Dr. Frank A. Payan of Providence, R. I., died on January 30, after an illness of three weeks. He was born in 1853 in St. Ours, Canada, but was graduated from Dartmouth Medical College in 1884, and since that time had practiced in Providence.

Dr. John Winsor of Quidnick, R. I., died on February 1 of tuberculosis, at the age of sixty-three years. He was born at Sterling, Conn., and had begun the study of Medicine at the Berkshire Medical College, at Pittsfield, Mass., when the War of the Rebellion broke out. He enlisted in the Twenty-sixth Connecticut Volunteers and later served with the Second Rhode Island Volunteers, resuming his studies at the close of the war and beginning practice in his native town. In 1870 he removed to Anthony, R. I., and later to Quidnick. He was for many years Health Officer of the town of Coventry, and was serving his fourth term as Medical Examiner for the First District of Kent County.

Dr. Julian C. Feild of Denison, Tex., died on January 31, of Bright's disease. Dr. Feild was born in Pulaski, Tenn., in 1841. After being graduated from the medical department of Tulane University, New Orleans, he served as surgeon in the Confederate Army. When Denison was first laid out as a town Dr. Feild located there and had since then served in many official positions. For thirty years he was local surgeon of the Houston and Texas Central Railroad.

Dr. Samuel R. Wooster of Grand Rapids, Mich., died on February 6, after a surgical operation. Dr. Wooster was born at Ansonia, Conn., in 1830, and was graduated from Yale College in 1857. He served through the Civil War as surgeon in several Michigan regiments, and after the close of the war went to Muskegon, where he practiced for several years, going to Grand Rapids at the end of that time. He held numerous government and local positions and was a charter member of the Grand Rapids Academy of Medicine, of which he was twice president.

Dr. Wm. Heverin Hobson died of typhoid fever at Philadelphia on January 30 at the age of thirty-six years. He was graduated from the Philadelphia College of Pharmacy and in 1895 from Jefferson Medical College. After graduation he became resident physician in St. Timothy's Hospital. He was married but five months ago.

Dr. Wm. G. Porter died of pneumonia at Philadelphia on January 30, at the age of sixty years. He was graduated in arts from the University of Pennsylvania in the year 1866, and from the medical department of the University in 1868. At once he became resident physician in the Philadelphia Hospital, and later was elected physician to the Philadelphia Dispensary. He was for many years surgeon to the Philadelphia Hospital and to the Episcopal Hospital.

Correspondence.

OUR LONDON LETTER.

(From Our Special Correspondent.)

THE ELECTION OF MEDICAL CANDIDATES—MILITARY HYGIENE ON ACTIVE SERVICE—INFANT MORTALITY—INCREASE OF LUNACY IN LONDON—NOTES.

London, January 26, 1906.

The turmoil of the general election is not yet over, but the result, as the cable has informed you, is an utter rout of the party which has so long been in office. The organs of both parties and some of the speakers pretended to be confident as to the result of an appeal to the people, but I am sure both looked forward to it with doubt, and both are amazed at the extent to which the political pendulum has swung. The medical candidates, as usual, were few, and their claims have been brushed aside with more than the usual indifference. Sir Michael Foster has lost the London University seat. This is no surprise, as his career offended the party which chose him. Sir W. Job Collins has found a seat, though he is unsound on vaccination. Sir George Robertson of Chitral fame has succeeded as has also Dr. T. B. Napier. Dr. C. F. Hutchinson, Surgeon-General Evatt, and Dr. J. Court have also failed. On the other hand, Mr. R. J. Price, Dr. R. Rainey, Dr. Pollard, and Dr. V. H. Rutherford have succeeded.

The Scottish Universities will not poll until next month. For Edinburgh and St. Andrews, Mr. Strachey has come forward to oppose Sir J. Batty Tuke, M.D., who did good work. Mr. Strachey rests his claim on free trade and the editorship of the *Spectator*, a paper by no means friendly to the medical profession, but he promises to be guided by the British Medical Association. In this contest men are found arguing against the idea of the profession voting for one of its members, even men who argue on behalf of the winning side. With a coming majority over all other parties put together, they grudge one seat for their own calling. The labor class has set them an example and shown that only union can secure representation.

"Military Hygiene on Active Service" was the title of a paper at the Royal United Service Institution by Major T. H. J. C. Goodwin, R.A., M.C. Having remarked that in the South African war we had 400,000 admissions to hospital from disease and only 18,000 for wounds, and spoken of water, food, flies, dust, and polluted soil as causes of disease, he discussed the remedies. He said there were two which would overcome the evil. (1) A specially trained sanitary corps, to which, subject to military exigencies, would be committed the selection of camping sites, installation of water supplies, and kindred matters. Sterilizers, filters, destructors, and, in fact, all sanitary appliances, should be under the care of this corps. (2) The spread of sanitary education among combatant officers, who were mostly quite ignorant of these matters. He did not blame them, as at home all sanitary requirements were carried out for them, and they were never required to consider the subject. The subject was of vital importance for the service.

Col. Davies, sanitary expert to the advisory board, agreed that the co-operation of combatant and medical officers was most desirable. It would be well if soldiers practised during peace maneuvers the sanitary operations and precautions necessary in war.

Surgeon-General Keogh, director-general of the medical service, who presided, said he did not believe in the necessity of a separate sanitary corps. He would rather see the officers and men of each battalion educated on the subject. He admitted, however, that during war it would be desirable to establish special sanitation detachments along the lines of communication and at the base. Sanitary science, properly applied, would enable a reduction to be made in the dead weight of hospitals and their personnel.

The last report of the County Councils' medical office for education contains some rather curious results of an investigation into the physique of about 400 boys attending a particular school, classified according to cleanliness, clothing, and degree of crowding in their homes. The lowest class graded in this way always proved inferior in height and weight to the general standard of the school, and the highest class was correspondingly taller and heavier. These results are in keeping with previous investigations, but of course are very limited in extent. But a comparison of the statistics, as far as they go, with the rates of infant mortality in the district of the school in question, brings out an unexpected result. The boys were grouped according to the year of their birth, and the lowest group were those born in a year of high infant mortality, while the converse obtained in the highest group. These figures might have been expected, as they agree with similar ones found elsewhere. The report suggests that the "adverse environment which slaughters one in five (of the infants born) has a maiming effect on those left."

While the general death rate in England has been falling, the infantile mortality has been rising in manufacturing and urban districts, though not in rural localities. This fact confirms the conclusion of the Deterioration Committee, that the cause is in environment, not in heredity. Children are generally born healthy, but housing conditions, improper food, etc., soon exercise their influence on them. So also it is generally thought the employment of married women has an evil effect on their offspring. The talk about national degeneracy receives no support from the report above mentioned, nor from other similar sources. Overcrowding, malnutrition, neglect, and such like influences are the causes of the high infantile death rate. Nor can it be longer maintained that degeneracy of race accounts for the statistics, for conditions which are fatal in the first year of life must exercise an evil influence on those they do not kill outright.

Closely connected with this subject is Dr. Alexander's valedictory address at the Gynecological Society. He spoke out in vigorous language what not a few are thinking, and proposed drastic remedies for the waste of infant life and the continual breeding of those who, born healthy, are sure to become degenerates. He would not have poor-law hospitals used, as they now are, by depraved women for their own convenience to bring forth children and kill them by neglect and drunkenness. He gave statistics of one Liverpool workhouse hospital, showing that in 1904, out of 388 births, 158 were illegitimate; of these, 106 were the mother's first child, 31 the second, 16 the third, 13 the fourth, 8 the fifth! This in one workhouse alone, and there are two others in Liverpool. In this one, no less than 158 illegitimates were thus added to the nation, "both mothers and children being fostered and cared for in a way that the mothers of even middle-class independent and hardworking people cannot afford." Some may think the majority of these die. Dr. Alexander said it is not so, and might be well if it were. But he followed up 304 such infants born in 1903, for a year, and found only 88 had died, leaving "216 out of one parish to pollute the population, and there are hundreds of such parishes." He went on to say that "not a word could the authorities say to these women, but must prepare aseptic conditions and the first-rate accommodation in the wards," and this, as he said, at the expense of the ratepayers, "the hard-working men and women who have to support them and their children, not only in the infancy of the latter, but as tramps and criminals into which they degenerate for the rest of their lives."

To remedy all this, Dr. Alexander would forbid people to marry who "cannot build a nest for their young." He has no sympathy with the sentimentalism which encourages the propagation of "human rubbish," or with agencies which make it easy to evade the scriptural rule that "he that will not work neither shall he eat." Further, he says the nation should insist on mothers nursing their children. That is the "birthright of the child," and as soon as it is born it is entitled to the "protection of the community, who ought to insist on its having its birthright whenever it is possible."

The apparent increase in lunacy in London has been before the Royal Commission on the Feeble-Minded in the evidence of Sir John McDougall, formerly chairman of the County Council and of its Asylums Committee. He went into the figures as to the increase of patients, and compared it with that of the population. With an approximate increase of 11.87 per cent. of the population in the last fifteen years, the pauper lunatics to be provided for by the Council had increased at the rate of 50.7 per cent. He attributed part of this to the frequent interchange of patients between the two bodies charged with their maintenance, and thought the dual control unsatisfactory. Further, there was an increased tendency to certify persons of weak minds, especially cases of mere senile decay, which only required nursing. It is a serious matter for the families of these aged persons to be considered lunatics in view of the question of heredity. The public having become convinced of the extreme humanity of the modern treatment of lunatics, has quite abandoned the old prejudice, and seems to be too ready to send to asylums those who are merely feeble-minded from advanced age. This is hardly a tendency to encourage. Considering the several points, it would seem that the increase of lunacy is more apparent than real.

Dr. L. A. Weatherly, who is superintendent of a private asylum, gave evidence to the commission as to feeble-minded criminals. He said such persons were often sent to prison three or four times before their mental condition was discovered. In prison it might not betray itself, and even after it had been found out and the patient sent to an asylum, he was often discharged after a short detention and again got into the hands of the police. This was because facts observed by the certifier are required to be stated; but if the history of the case could be considered, it would often clear up the matter. Police surgeons seldom see a case until three or four convictions have occurred, and then they are expected to report after a brief interview with the accused. A prison is not the place for such persons; it has no deterrent effect on them. Nor is an asylum, as such are at present constituted. Dr. Weatherby advocated special penal colonies, and said these feeble-minded criminals properly supervised would do a considerable amount of useful work and would greatly benefit by doing it.

A course of lectures and demonstrations on the duties of army medical officers was begun on Saturday, at the West London Hospital by the director-general, in response to a request by a number of civil surgeons who wished to fit themselves for acting as a reserve for the Royal Artillery Medical Corps, in case of such services being needful during a great war.

Faddists often give us occasion to smile at their notions. It seems amazing, for instance, to notice that at the annual meeting of the Vegetarian Society, the president remarked that the good seed sown by them during eighteen years was producing fruit abundantly, so that now they "were advancing in battalions of food reformers, hygienists, antivaccinationists, anti-smokers, and abstainers from alcohol." Truly a motley army.

The attitude of the new government on vaccination is speedily producing effect. The Wandsworth Board has already addressed the Local Government Board, asking leave to enter into contracts with doctors who will take less than the authorized fees.

The Hospital Saturday Fund has accepted the recommendation of the distribution committee to award $23,636 between the 202 participating institutions.

THE PRINCIPLES OF ETHICS.

To the Editor of the Medical Record:

Sir:—In the Medical Record of January 27, I notice an editorial on "Medical Ethics." I am sure we are all happy that the New York profession is at last reunited, and I was sorry to see that this old question was brought up again, as it might stir up some bad blood. I perfectly agree with you that there are a lot of small things in it that might just as well be left out. The fact is that *you* know all about it and *I* know all about it; *we* do not need it. We have had the experience. If you will think away back when you were a student or had just graduated, how little you knew about it. You knew what was right and proper, but the hundreds of little details you did not know. If you had been taught them properly and studied the code of ethics, you would have saved yourself many a trouble. The code of ethics is for the *young man* who just starts out in practice. By studying it and remembering it, it will prevent him from doing many tactless things he otherwise would do thoughtlessly. I get around the State a good deal, to the small towns and villages, and then hear from the physicians how a young man comes into the town, and does not know enough to call on them and introduce himself. How he took a patient away, and did other unethical and untactful things. When I talk with the young doctors about it they are perfectly amazed. They did not think they did anything wrong. They never looked at it in that light. So the Detroit College of Medicine has made it a rule to give every year a series of lectures on the "Principles of Ethics," which does the students a world of good in their future career and saves them many heartaches and troubles. Hence I beg of you, let the "Principles of Ethics" stand as a guide to the young men in the profession. You might boil them down, you might change the phraseology, but the principles laid down in the "Letter of a Physician to His Son," written one hundred years ago, are as good to-day as they were then.

Detroit, Mich. J. H. Carstens, M.D

QUININE IN CHOLERA.

To The Editor of The Medical Record:

Sir:—Among the older readers of the Medical Record there are doubtless some who will be glad to learn that my prediction made at various times, chiefly in this journal, that under varying circumstances the mortality from Asiatic cholera should fall somewhere between 2 and 25 per cent., has been fully verified, by the report of Dr. Ussher, a medical missionary at Van, in Asiatic Turkey. About one year ago he there treated a most malignant outbreak of the disease with 100 per cent. mortality, for the first week of the epidemic. At midnight Saturday he began with my quinine treatment, losing less than 10 per cent. of his cases thereafter. (See *Journal of the American Medical Association* for February 3, 1906, page 361.)

It seems to me that after fighting the battle alone for thirty-three years, I should have some assistance from others having as much interest in humanity and the honor of the American medical profession.

Erskine B Fullerton, M D.

Columbus, Ohio.

Progress of Medical Science.

Boston Medical and Surgical Journal, February 8, 1906.

Vaginapexy.—This operation, as described by W. P. Graves, is the stitching of the vagina to the abdominal wall and is applicable to cases of extreme vaginal relaxation, such as prolapse, incomplete and complete procidentia and advanced cystocele. From a year's experience with the operation the author says that in not one single case, even where there has been extreme anteversion or much tension on the vagina and abdominal wall, have there been any bladder symptoms whatsoever, but, on the contrary, cases in which there were distressing bladder symptoms due to the accompanying cystocele, have been completely relieved in a comparatively short time. It may also be said that the anteversion itself disappears in a very few weeks, and examination shows the uterus to have settled into its normal position with regard to its longitudinal axis. With regard to the possible dangers which might ensue in case of a subsequent conception, the author is guarded in his statements. None of his patients have become pregnant since the operation. The indications for the latter are present in all cases where the vaginal attachment to the rami of the pubes has completely or incompletely given way and would, therefore, imply conditions of marked prolapse, complete or incomplete procidentia with accompanying cystocele. The number of operations done at the hospital with which the author is connected is 19. While it is too early to claim a complete cure for those recently done, the results as observed are extremely satisfactory and far exceed in value for a proportionate length of time the results of operations formerly employed for the relief of prolapse, procidentia, and cystocele. The technical steps of the operation are described in full in the paper. An illustration shows the sutures in position.

Contractile Processes in the Lung as a Result of Phthisis, with Reference Especially to their Production of Permanent Dextrocardia.—H. B. Dunham has collected the reports of about twenty cases of acquired dextrocardia as the result of chronic contractile pulmonary tuberculosis. In all, the right lung was the seat of the disease, which always seemed to be of a chronic fibroid type, with sclerosis of the lung tissue and bronchiectasis. The left lung has always seemed sound or but very slightly affected. Examination has shown, however, an augmented volume of the left lung, a fact which, in the author's judgment, is a potent causative factor of the complication. Detailed histories are given of two cases. In one the change of the heart to the right side was gradual and unnoticed other than the fact of a realization on the patient's part that the heart was beating upon the right side instead of left, where he had ordinarily been accustomed to feel it. In the other case transposition was sudden, at least in part, because the patient was conscious of the change in position, which occurred during a coughing attack, which he had while working, and he felt something move in his chest toward the right side. If coughing was responsible in any way for the movement within his chest, then certainly augmentation of volume of the left lung must have been a more important factor at that instant than the adhesions or slerosis of the right lung, which occurred but gradually. From observation of these two cases the author is inclined to believe that the emphysematous enlargement of the left lung was not merely a passive filling up of unoccupied thoracic space due to contractile processes on the opposite side, but to an attempt at genuine compensatory hypertrophy, which would cause slight pressure on the heart and the opposite incapacitated lung.

American Medicine, February 10, 1906.

Arteriosclerosis as a General Disease.—Alfred Stengel says the conception of arteriosclerosis as merely a passive process of hardening of the vessels is now completely out of date. A proper picture of the condition portrays a more general disturbance of the whole organism. Three stages of the disease may be recognized. 1. A preliminary one difficult of recognition in its beginnings and confusing to the clinician in his first efforts to distinguish what part the etiologic factors have contributed to the symptom-complex and what part has resulted from the arterial disease itself. 2. A middle period, during which the arterial disease is easy to recognize, but in which secondary organic changes have a role of variable importance. 3. A final stage of failure of circulation, organic failure and terminal infection. Arteriosclerosis as ordinarily seen begins in middle or later life, progresses regularly and slowly, involving all the vessels uniformly and causing a coincident involution of the body as a whole. Contrasted with this is the form seen in younger subjects, more rapid in its course, showing a tendency to the greater involvement of certain vessels causing notable functional disturbances. In this form especially are the general changes quite out of proportion to the arterial involvement. Some investigators have insisted that there is a preliminary presclerotic stage of continued high blood pressure attributed either to a spasm of the arterioles due to toxic or nervous influences or to a change in the viscosity of the blood causing obstruction to the circulation. Dr. Stengel's clinical studies have shown that in the earliest stages there is rather a condition of decreased tension with a tendency to temporary or paroxysmal elevations, that the condition is one of loss of elasticity in the vessels due in part to toxic alterations (degenerations) in the vessel walls. Among the varieties of early arteriosclerosis he has observed several more or less distinct types. The nutritional type presenting obscure disturbance of general health with a tendency to digestive disorders and anemia or pseudoanemia. The neurasthenic type with or without definite nutritional disorders. The nervous type with the tendency to vertigo, tinnitus, syncopal attacks in early stages or temporary paralysis, spasmodic or convulsive disorders, or disturbances of consciousness in advanced disease. In the more advanced stages of arteriosclerosis the disease may be classified under the following headings: (1) Thoracic; (*a*) cardiac or disturbances incident upon special involvement of the coronary arteries; (*b*) aortic, referring not merely to aneurysm, but also to a sclerotic and calcareous roughening without dilatation, but causing embarrassment of cardiac action. (2) Abdominal; (*a*) renal, manifesting itself in the symptoms of chronic interstitial nephritis; (*b*) intestinal, as evidenced by atrophy of the mucous membrane, tendency to chronic colitis, etc.: (*c*) pancreatic, difficult of recognition, often, however, active in diabetes; (*d*) hepatic, occurring as cirrhosis; (*e*) cerebrospinal, most numerous and varied, and (*f*) arteriocapillary, manifested in moderate circulatory disturbances.

Treatment of Mediastinal Carcinoma with the Röntgen Rays.—G. E. Pfahler reports six cases in which carcinoma of the mediastinum developed secondary to carcinoma of the breast. All of the patients had been previously operated upon. The diagnosis of mediastinal carcinoma was confirmed by consultation and by radiographs. One patient had palsy of the left arm, due to pressure of deep-seated cervical glands upon the cervical plexus. Treatment was directed to these glands as well as the mediastinum and was followed by what appears to be complete recovery. Three of the six patients have apparently recovered, though they are still under observation. In none were any bad results noted. Fifty per cent. of recoveries in an otherwise fatal disease, for which other forms of treatment offer no hope, justifies us in recommending this form of treatment to patients as early as possible.

Cerebrospinal Meningitis.—Geo. C. Merriman makes a strong plea for more thorough examination of the spine in cases in children which appear to be of pneumonia. He firmly believes that the enormous percentage of mortality in pneumonia among children has been due, in many instances, to unrecognized meningitis. In every case of acute lung involvement in children a careful examination should be made of the spine and neck and eyes. Pressure over the spine and at the base of the skull will bring out the tenderness in the cervical and dorsal regions. Examination of the eyes will sometimes, not always, show some inequality in the pupils, and the presence of photophobia. The finding of these symptoms in a case that appears to be pneumonia will put a totally different complexion on the case, and will change the entire outlining of the treatment. He reports at length a typical case which occurred in a child of six months.

The Edibility of Animal Spleens.—E. J. Williams, in the course of investigations on animal spleens, found them good to eat. He cooked them in various ways and tested them on his friends. They contain ¾ gr. of iron and ½ gr. of phosphorus per ounce. When raw they have a pulpy consistency which renders them unfit to eat. Heat coagulates their free albumin, and gives them a consistency to be cut and chewed. They must be eaten quite fresh. They decompose rapidly and cannot be kept over night, even on ice. To be safely eaten they must of course be healthy. All infectious diseases are liable to affect the spleen. All diseased spleens should be rigidly excluded. Dr. Williams concludes with general remarks on the dietetic value of spleens as a blood-making food.

Journal of the American Medical Association, February 10, 1906.

Ligature of the Common Duct.—Two interesting cases are reported by J. Ransohoff, in both of which there was apparently developing general peritonitis, supposedly of appendical origin. One, however, proved to be a case of gangrene of the gall-bladder, with no trace of gallstones and

with sterile contents. The gall-bladder sloughed away, almost *en masse*, five weeks after the operation, the wound closed and the patient made a good recovery. In the other case, there proved to be a tear of the common duct, allowing the escape of free bile in large quantities into the peritoneal cavity. It was probably due to a gallstone, though none was found. Both cases emphasize the fact that in the presence of peritonitis, a doubt as to its source makes for, rather than against, the advisability of operation. Ransohoff discusses the effect of bile on the peritoneum, and concludes that it is by no means an innocuous agent. He also calls attention to a symptom present in this case, the local jaundice of the umbilicus, which he thinks may be of value in diagnosis. It is probably the result of imbibition, and shows itself first at the navel because of the thinness of the abdominal wall at that point.

Amputations Below the Knee.—C. D. Clapp, having had several occasions to make leg amputations because of a painful Chopart stump, addressed letters to a number of surgeons and instrument makers requesting their opinions as to the various operations for partial or complete amputations of the foot. Considerable difference of opinion was elicited, and a wide variance between artificial limb makers and surgeons, which was especially noticeable in regard to the Symes operation. He thinks the opinions of the leg makers are worthy of considerable respect, as they often see more of the after-treatment than the surgeon. Clapp believes that the old theory of saving all that one can is absurd as applied to amputations below the knee, and that an ideal leg amputation is superior to many Chopart or Symes and most Pirogoff amputations. The Lisfranc operation, especially the Hey modification, gives a good stump, but Clapp advises preserving the attachment of the tibialis anticus when possible, and if not, to attach its tendons to the plantar flap. The same rule applies also to the peroneus tertius. He lays down the following points as essential in amputation of the leg: 1. Be certain of sufficient flap properly to cover the end of the bone, regardless of how close this may come to the knee joint. The flap must be considered first, length of stump second. 2. The most uniformly good results are obtained by making the long anterior with short posterior flap, bringing the scar well away from the end of the stump. 3. Redundancy is always undesirable. 4. When the length of stump is at the discretion of the operator, it should be from 6 to 9 inches below the lower border of the patella. 5. A periosteal flap, with coaptation of muscles over the end of the bone is always desirable. 6. The fibula should always be cut one inch shorter than the tiba, and when the amputation is near the knee joint, the fibula should be disarticulated and removed. 7. In all these amputations, nerves should be drawn out and cut as short as possible.

Pneumonia.—W. J. Galbraith says this is one of the foremost diseases to be considered by the medical profession, and he disagrees entirely with those who favor the expectant methods in its treatment. The first and the continued effort, he thinks, should be to fortify the heart and to destroy the germs and their products that produce sepsis. The chief thing in the treatment he advises, is that it prevents septicemia. His method, as summarized by him, is as follows: First a warm bath, followed by a calomel or phosphate of sodium purge. The first dose of quinine is given three hours later, provided the stomach is not disturbed. If the temperature is 105° or over he gives from 60 to 70 grains of quinine sulphate, followed in an hour by usually half the same dose. If the temperature ranges between 103° and 104°, from 40 to 50 grains are given as above. If a lower temperature is found, he gives 40 grains, his minimum initial dose. The use of the tincture of the chloride of iron is begun within three or four hours after the second dose of quinine, and in doses ranging from 10 to 15 minims at intervals of from two to six hours, depending on the condition of the pulse. In case the temperature rises to 101° or 102°, after it has reached the normal or subnormal mark, he administers from 40 to 50 grains of quinine at one dose and continues the iron in 15 minim doses every three or four hours. He protests against any compromise in the way of dividing the doses of either iron or quinine during the active pneumonic stage. If the stomach is rebellious it may usually be overcome by pepsin and guaiacol. He dresses his patients with as light-weight clothing as possible and provides thorough ventilation and advises plenty of liquid nourishment.

A Physicochemical Theory of Fertilization.— First defining fertilization physiologically as the impulse to development, M. F. Fischer and W. Ostwald argue that the essential morphological part of fertilization is the formation of the astrosphere and that it is to this that the impulse to development is due. They also believe that they can demonstrate that all the methods which can be used to bring about the formation of an astrosphere in an egg or its development are such as can be employed to bring about the conversion of a liquid colloid or sol of the approximate constitution of egg protoplasm into a solid colloid or gel, and that conversely, almost every method which physical chemistry has at its disposal to bring about the conversion of a sol into a gel is or may be used to bring about the normal or artificial development of the ovum. The formation of the astrosphere, or, according to their view, the process of fertilization, is identical with a localized and oriented gelation. In normal fertilization the impulse is furnished by the spermatozoon, or rather by its middle piece; in natural parthenogenesis the polar bodies which are not thrown off as in the former case seem to assume under certain conditions the gel-producing function of the middle piece of the spermatozoon, and in artificial parthenogenesis the impulse is supplied by certain physical or chemical stimuli, such as withdrawal of water, or mechanical stimuli. The authors believe, in opposition to some other biologists, that in all cases specific external conditions determine the development of the unfertilized egg, but that the colloidal solutions of the egg protoplasm lie exceedingly near their critical, that is to say their coagulation.

Suture of Heart Wounds.—J. H. Gibbon makes a third contribution to the subject of penetrating wounds of the heart, reporting his second case of suture of the heart and his first successful one. The patient, a healthy colored man, aged thirty-eight, had received a penknife wound in the right ventricle of the heart. Hemorrhage had been spontaneously controlled to some extent by pressure of the clot and liquid blood in the pericardium, and was readily controlled by digital compression during the operation, though the wound in the external surface of the heart was from half to three-fourths of an inch in length, and apparently half as extensive in the endocardium. The heart was held firmly against the pericardial opening with a traction suture of chromicized gut and four other sutures introduced with an intestinal needle closing the whole thickness of the wound in the heart wall. The patient was out of bed in two weeks, and was discharged in twenty days after the operation. At present he is well, and the heart action is normal. The pleura was uninjured, either by the wound or in the operation, no osteoplastic flap having been made, but merely excision of costal cartilage. In a future similar case, Gibbon would not attempt to drain the pericardium. The external wound, however, he thinks, should always be drained. Whenever there is suspicion of a wound of the heart an exploratory operation should be made. Gibbon advises against any too vigorous stimulation when wound of the heart is suspected.

The Lancet, January 27, 1906.

Interrupted Circulation as a Therapeutic Agent.—This plan of treatment is considered by W. Ewart, with special reference to rheumatoid arthritis. In the absence of an Esmarch's tourniquet the simplest substitute is India rubber tubing of suitable thickness, which is tightened around the limb in single or double loop outside a slight protecting pad. The duration of the constriction varies from half a minute to five minutes. Three applications at each sitting may suffice in most cases and two sittings daily may be desirable. No complications have arisen in the author's experience. The plan is contraindicated in patients with inflamed or tender nerve trunks or senile and calcified arteries. The following clinical results were noted: (1) Recent puffy swellings were rapidly amenable to a few applications, and in one case to a single application; (2) the inveterate puffy swelling associated with fibrous, cartilaginous, and bony thickenings was sometimes visibly influenced during the application. Its almost complete disappearance after a short series of sittings revealed the articular deformities in their sharper nodular outlines. (3) The periarticular thickenings were slower to yield but gradually diminished. (4) The thickening of cartilages and of the joint ends of bones may conceivably be found to yield to prolonged treatment. At any rate, some reduction has been observed in the diameter of the float-shaped knuckles and of the swollen wrists and knees in one case. But how much of this fining down may have been confined to the periosteum cannot be decided without more searching observation by means of systematic radiography. (5) The great improvement secured with the help of this method in the condition of the articular surfaces in conditions of absolute rigidity from adhesions, both as regards restoration of movement, diminution of crackling or grating, and actual reduction in the size of the joint as a whole, was evidenced in one case. (6) In connection with the latter case, attention may also be called to the fact that in limbs

so long disused all the tissues must benefit indirectly from the restoration of movement, in addition to any direct advantage conferred upon them by the tourniquet.

Acid Extract of the Duodenal Mucous Membrane as a Remedy in Diabetes Mellitus.—Three cases are reported by J. H. Abram. In all the results were favorable and seemed to justify a continuance of the remedy in the disease named. The author started with the demonstrations of Bayliss and Starling, who have shown that the contact of hydrochloric acid with the epithelial cells of the duodenum causes in them the production of a body which is absorbed by the blood stream and carried to the pancreas, then to act as a specific stimulus to secretion. He says that we do not know whether the internal secretion from the pancreas is derived from special cells or from the ordinary cells of the organ. We do know, however, that an active pancreas pours a larger amount of lymph into the efferent vessels, and this may include an increase in the internal secretion. We know also that the duodenal mucosa, pancreas, liver, and muscles are all concerned in carbohydrate assimilation. It is difficult in any given case of diabetes to determine which of them may be at fault; moreover they are all under the control of the nervous system, either directly or through the intervention of the blood-vessels. It is impossible, therefore, to say in any particular case, whether the acid extract will prove useful or whether combinations of extracts of these organs may be necessary.

A New and Easy Process of Triple Staining for Cytological and Histological Purposes.—The process is thus described by V. Bonney: (1) Fix small pieces of tissue in acetic alcohol (glacial acetic acid, 1 part; alcohol, 2 parts); (2) imbed, cut, and mount in the usual manner; (3) stain for one hour in a saturated watery solution of saffranin; (4) wash in water; (5) stain for a quarter of an hour in a saturated watery solution of methyl violet; (6) wash in water and wipe the slide dry except that part occupied by the section; (7) have ready in a drop-bottle the following solution: to 20 cubic centimeters of acetone add drop by drop a saturated watery solution of orange G. until the flocculent precipitate which slowly appears on shaking is just dissolved in excess of the watery solution; then filter; (8) flood the slide with this solution. A cloud of color immediately comes out, which obscures the view of the section; (9) pour this off on to blotting-paper and flood again with the same solution. The color cloud being much fainter the section can be watched. (10) When the section has attained a rather faint brownish-pink color, pour off the orange-acetone solution; (11) Wash in acetone for a few seconds. (This should be contained in a small glass jar. Acetone being very volatile, care should be taken that the section does not dry.) (12) Wash in xylol; (13) transfer to low-power microscope and see if the proper result has been attained; (14) wash in two fresh changes of xylol; (15) mount in xylol-balsam. Result: All chromatic elements, nucleoli, and certain nuclei, such as those of polymorphonuclear leucocytes, stain a rich violet, chromosomes standing out with peculiar distinctness. The spindle fibers of nuclear mitosis stain a faint pink. The cytoplasm stains a rose pink. The intercellular tissue stains a pale yellow. These effects are best seen if the slide be examined through a deep blue screen.

The Importance of a Strictly Limited Lactation.—Statistical tables are presented by A. D. Fordyce based on 405 children from 100 mothers. His general conclusions are as follows: (1) The concurrence of pregnancy, with lactation is comparatively common. (2) Conception is rare within the first six months of lactation and uncommon before the eighth month. (3) Where pregnancy and lactation overlap the fetus is likely to suffer. That every case must be judged on its own merits is a truism, but given fairly average conditions, a strong healthy suckling, and the prospect of intelligent hand-feeding, the above facts point very strongly to the advantages to be derived from weaning early in the eighth month.

British Medical Journal, January 27, 1906.

New Treatment for Housemaid's Knee.—F. J. Allen advocates the familiar subcutaneous rupture. He has tried it twice on his own person. Once by the blow of a boot and once by deliberately kneeling on the affected joint. The latter procedure he declares to be painless. If the bursa tends to fill again, gentle pressure will dissipate the fluid, and through the artificial opening a free communication is apparently established between the bursa and the adjacent lymphatics.

Epistaxis and Calcium Chloride.—A. T. White records the case of a man of 60 years, of a distinctly apoplectic type and with athermatous arteries who suffered from several severe nosebleeds. Apart from some rhinitis there was no nasal lesion. The author was loath to cauterize the nose, as apoplexy has followed in some cases so treated, so he prescribed calcium chloride in 10-grain doses thrice daily for ten days with permanent relief to the attacks of epistaxis.

Chloroform in Consumption.—Noting the good effects in consumptives following the administration of chloroform for anesthesia J. Holmes has been led to surmise that this volatile remedy may prove to be a distinct germicide in the condition obtaining in pulmonary tuberculosis. He suggests the use of the remedy as an inhalent mixed with a little eucalyptol and terebene to disguise the color and smell. Results have been uniformly good, but only in the palliative sense. The inhalations must be frequently repeated. The author believes that many bacilli may not be killed at each inhalation, but thinks it likely that they are so weakened as to fall an easy prey to the phagocytes. Chloroform, being very volatile and a parasiticide, ought to be an ideal drug for use in the lungs when bacilli are to be destroyed. Of course food and fresh air must not be overlooked.

Simultaneous Excision of Two-thirds of the Stomach, the Anterior Face of the Pancreas and the Transverse Colon for Carcinoma.—An account of this remarkable case is given by C. P. Childe, whose patient was a woman of thirty-five years. The colon was excised, not because it was itself involved in the disease, but because of the necessity of sacrificing its blood supply in order to get rid of the growth. Full details of the operation are given, but they cannot be reproduced here. The patient was somewhat collapsed at the end of the operation, but quickly rallied under an intravenous saline injection. Convalescence was uneventful. Stitches were removed on the eighth day, primary union having occurred. She was nourished entirely by the rectum during the first forty-eight hours. After this small quantities of liquids were given by the mouth, and at the end of fourteen days she was taking light solid foods. Five weeks after the operation she was doing well in every way.

Diagnosis and Treatment of Swellings of the Breast.—A. Clark enumerates as the various conditions which bring women to the doctor with the statement that they have a swelling in the breast, as neuralgia, mastitis, abscess, adenoma or fibroadenoma, cysts, and malignant disease. We are most perplexed in diagnoses between chronic mastitis and carcinoma. There are some cases in which a preliminary incision (when the patient is ready for a more extensive operation if necessary) is the only course to follow. Neuralgia is rarely met with, except in neurotic young women, and is nearly always associated with menstrual troubles, the pain being more at the periods. Acute mastitis presents the usual febrile condition, while chronic mastitis often causes much perplexity. It is often of an interstitial nature, with hypertrophy and thickening of the connective tissue, a sort of fibrous degeneration of the breast. Often the condition leads to duct compression and cyst formation. Abscess is generally made out without difficulty, unless it has assumed a chronic, localized form. Cysts may occur either from retention or as an expression of involution at the climacteric. The latter are movable with the breast, the skin moves over them, the hardness is variable, depending on the amount of fluid and the thickness of the cyst wall. The contents are often glairy and of a reddish-brown color. Cancer may be either acinous, or glandular, or duct cancer. Most of them are hard and scirrhus. Detailed characteristics of each are given along the usual lines. The author is an advocate of early operation, including the axillary contents in the parts to be removed. Some cases call for removal of the pectoral muscles, but the author deems it inexpedient to divide the clavicle.

Berliner klinische Wochenschrift, January 22, 1906.

The Treatment of Pulmonary Tuberculosis with Marmorek's Serum.—Stadelmann and Benfey say that although numerous authors have published observations favorable to the use of Marmorek's serum for the treatment of tuberculosis, their own experience with the remedy has not been satisfactory. Their observations were made in five cases presenting various stages of the disease, but the use of the serum was attended by such undesirable effects that they did not feel justified in pursuing the investigation further and subjecting a greater number of patients to the injections. The administration of the serum was followed by more or less protracted and severe elevations of temperature; local lesions of considerable gravity were noted about the site of injection; and itching urticarial eruptions, swelling of the lymphatics, and dizziness and nausea were other undesirable sequelæ. The cough, expectoration, and night sweats remained unchanged, but the general condition of the patients was altered for the worse, and though they recuperated promptly on stopping the injections, they in several instances refused to submit to further treatment in this way. The serum was obtained from Marmorek himself

and the injections were carried out strictly in accordance with his directions.

The Action of the Anticomplements.—Moreschi supplements his former observations on this subject by reporting the results of further experiments in the same direction. In these the amboceptor was furnished by the inactivated serum of rabbits adapted to washed goat corpuscles. The precipitin used was that of serum of rabbits treated with inactivated normal goat's serum or with egg albumen. The precipitinogen was normal inactivated goat serum and the complement normal guinea pig serum. The corpuscles employed were goat corpuscles washed three times in salt solution and used in 10 per cent. dilution. The conclusions reached were as follows: Precipitin and precipitinogen unite in variable proportion and form a series of precipitates exhibiting a more or less active anticomplementary action. All circumstances leading to a more pronounced precipitation involve an increase in the anticomplementary action. The immune body is not modified by the precipitate. In dealing with hemolytic sera the phenomenon of deviation of the complement noted by Neisser and Wechsberg for bacteriolytic sera may also be observed, but in this case the deviation of the complement is effected not through the excess of immune body, but through the specific precipitate. Anticomplementary sera in the sense indicated by Ehrlich and others, are precipitating sera.

Münchener medizinische Wochenschrift, January 23, 1906.

A Case of Subcutaneous Rupture of the Intestine Cured by Operation.—Hoepfl reports this remarkable case. The patient was a miner twenty-five years old who, five hours after his last meal, received a severe blow in the abdomen from an iron lever with which he was engaged in moving a coal car. He was knocked down and experienced violent abdominal pain, but got up again and continued performing his usual heavy work at moving the cars for some time longer. He was finally obliged to desist on account of pain and nausea, but walked to the hospital, a distance of over half a mile from the point where he was working in the mine. On admission, although an abdominal injury was suspected, his general condition was so good that operation was deferred. The next day, although the patient had been placed on strict starvation diet, he was by mistake given a small plate of cauliflower soup for which his great hunger had led him to beg. Shortly after this severe abdominal pain set in and the abdomen became much distended. A laparotomy was then performed, over twenty-four hours after reception of the injury, and it was discovered that the small intestine was the seat of a transverse rupture two and one-half cm. long from which intestinal contents were flowing out, while the entire abdominal cavity was filled with liquid feces. The intestinal wound was sutured, and after eventration of the intestine the abdominal cavity was flushed out with large quantities of salt salution, gauze drains were inserted, and the wound was left partly open. After a rather protracted convalescence the patient was discharged with the wound completely healed, and in condition to do light work. Three years after the original injury the patient was the victim of a fatal accident in which he was crushed by a flywheel. At the autopsy a broad band of adhesions was found uniting the small intestine about the region of the former injury to the abdominal scar. The author attributes the comparative euphoria which existed for the first hours after the accident to the fact that the patient's intestine was empty, so that but little escape of intestinal contents took place.

Appendicostomy.—Lanz bases his conclusions on 1,286 cases of appendicitis and 710 appendectomies. He has not lost a single case after operation and has had only a single instance of fecal fistula in the series. While he is an advocate of early operation, he believes that it is of the utmost importance to render operative intervention free from danger, and with this end in view he prefers to operate only at the very beginning of the attack or in the interval. It is only in exceptional cases that he allows himself to be persuaded to operate during the attack, and he then confines himself to incision of the abscess or drainage of the peritoneal cavity. After light attacks that have been under his own observation and unaccompanied by exudate, he operates as soon as the patient has recovered from the attack and regained his strength; if there is exudate, but this promptly subsides, he waits at least a month, and if the mass is slow to disappear, he waits for three months after the termination of the attack before performing the radical operation. He emphasizes the necessity for dosage of operations as of drugs, and considers it desirable never to overtax a patient's powers of recuperation by a too protracted operative procedure. One means of avoiding difficult dissections in cases ill suited for prolonged anesthesia is found in what he terms appendicostomy. If the appendix is buried in a mass of adhesions from which it would be difficult to liberate it, or it forms part of the wall of an abscess cavity, the author believes that in certain instances, as he has proved by experience, it is wiser to cut it through at the base and treat the cecal stump in the usual way, but to bring the distal portion of the appendix out of the wound, leaving its tip still buried in the adhesions. The wound may then be closed and at a much later date it will be found that through a process of shrinkage and fibrosis the appendical stump may be extracted without difficulty and without subjecting the patient to any risk. Any pus present will be found to have become sterile and to be no longer a source of danger.

Studies on the Leucocytes of Human Blood.—Schridde states that in order to arrive at satisfactory conclusions in regard to the origin of the leucocytes it is necessary to study the bone marrow not only in smears but also in sections. This has heretofore not been feasible on account of the difficulty of securing adequate differentiation by the staining methods in use, but the author has devised a method involving the use of azur II-eosin and acetone by means of which it is possible to demonstrate these granules successfully. His studies lead him to believe that the polynuclear leucocytes are derived from myelocytes or myloblasts by a process of differentiation of their protoplasm and granules. He holds firmly to Ehrlich's view of the individuality of the three types of leucocytic granulations and is convinced that these never change from one type to the other. The lymphocytes are to be considered as an entirely different race of cells and originate in entirely different prototypes. The lymphoblasts of the germinal centers in the lymph follicles form only lymphocytes and the myeloblasts produce only leucocytes. Normally leucocytes are formed only in the bone marrow and it is only under exceptional conditions that they are also elaborated in the perivascular tissues of other organs. The author attaches considerable importance to the observation that by means of his staining method it is possible to obtain satisfactory pictures of lymphocytes actually in the process of passing through the capillary walls, and he ascribes to these cells as well as to the leucocytes the power of active motion.

Deutsche medizinische Wochenschrift, January 25, 1906.

Observations on Frambœsia Tropica.—Castellani supplements his previous communications concerning the presence of spirochetes in the lesions of yaws by a further report fourteen cases of typical frambesia were examined, and in eleven instances spirochetes were found in the cutaneous lesions. Among these there was one very delicate variety which could be found in unbroken lesions without the presence of any other organisms, and Castellani believes that at present it is not possible morphologically to distinguish this organism from the *Spirochæta pallida*. As he is of the opinion, however, that frambesia is a different disease from syphilis, he states that should this spirochete be found of etiological significance in frambesia it must be different from the one of syphilis. He suggests for it the name *Spirochæta pertenuis seu pallidula*. Castellani in closed lesions also found in some instances peculiar oval or rounded bodies from four to eight μ in diameter, though larger and smaller ones are also observed, which stain light purple or blue with Leishman's stain and contain chromatin. It is possible that these may have some connection with the life history of the spirochetes. Ulcerating lesions were found to contain countless bacteria and several varieties of spirochetes. One of these is identical with the *Spirochæta refringens* and to another the author gives the name *Spirochæta tenuis obtusa* and to another the name *Spirochæta tenuis acuminata*.

A New External Hemostatic.—Schädel speaks well of the use of potassium permanganate as a hemostatic which was recommended recently by Vörner. The remedy was first applied in powder form mixed with charcoal in the proportion of three to one; but it was later found more convenient to use it in the shape of a paste. This may advantageously be prepared by the addition of about 4 per cent. of vaseline. The efficiency of the preparation appears to be somewhat impaired if it has been long exposed to the air. It has been used with good success in all forms of parenchymatous hemorrhage such as follows the excision of condylomata, warts, etc. It has also been found of value in nasal hemorrhage and in lupus. The hemostatic is applied by carefully drying the spot in question and then pressed some of the paste directly onto the bleeding surface. Slight burning is caused, but the sensation is not very painful.

Agglutination in the Hands of the Practitioner.—Loele describes the technique of making serum reactions by the aid of dead cultures. For the Widal reaction the process is as follows: The culture fluid is secured by spreading the necessary amounts of emulsion of typhoid bacilli over the surface of large agar dishes. At the end of twenty-four hours the mass of bacterial growth is flooded with a solution containing 2 per cent. of formalin and 6 per cent. of sodium chloride. This suffices to kill the bacilli, and the fluid is then filtered through coarse filter paper. Such a

preparation preserved at room temperature was found by the author to have lost none of its agglutinating power at the end of a year and a half. In order to carry out the reaction a capillary tube is used, one end of which is arbitrarily graduated into twenty equal parts. Nine such parts of formalin sodium chloride solution of the strength noted above are put into a suitable small tube and the patient's finger or ear is punctured. A suitable amount of blood is allowed to flow into the capillary tube, the number of divisions filled being noted. The blood is immediately blown into the formalin solution and enough of the solution is added by means of the capillary tube to make a 10 per cent. blood mixture. The preparation is set aside for a few hours in order to let the corpuscles settle, and then, using the same graduated capillary tube, suitable quantities of the fluid are added to a measured amount of the formalized culture in order to make the desired dilutions. It is to be remembered that the agglutinating power of whole blood is only about half as great as that of serum alone, and allowance must be made for this fact in preparing the dilutions.

French and Italian Journals.

An Unusual Case of Hereditary Syphilis.—F. de Queiros Mattono reports the history of a case of this nature. The patient was a child four months old. It was in an emaciated condition and had suffered since birth with dyspnea, which was exaggerated by muscular effort, by shrieking, crying, and so on. By exclusion, the diagnosis of hereditary laryngeal syphilis with respiratory stenosis and congenital wheezing, was made. At two different periods twenty-five injections of biniodide of mercury, five milligrams at a dose, were administered. This medication controlled the symptoms and brought about a decided amelioration of the condition, thus helping to confirm the diagnosis. After an investigation into all other causes of laryngeal stenosis, with negative results, the nature of this affection was determined.—*La Tribune Médicale*, January, 1906.

Tumor of the Left Breast in a Man.—Prat had this patient under his care. The man was sixty-five years old, strong, and inclined to be obese. Some months ago he was discovered to be suffering from diabetes, but after following a strict regime for some time the urine showed only slight traces of sugar. The lesion of the breast first appeared about ten years ago when a small swelling appeared which was sometimes annoying, but rarely painful. The swelling was considered benign, and for a long time it remained stationary. Four years ago examination showed it to be the size of a nut, and movable. The nipple was slightly retracted. At that time the diagnosis of malignant neoplasm was made and ablation was advised. In September, 1905, the tumor had increased greatly in size and was a mass as large as the fist. The skin over it was movable. The tumor itself was movable over the chest. The nipple was completely retracted. The neighboring ganglia were not appreciably enlarged. Operation was performed within a few weeks. Convalescence was uninterrupted. The tumor, after a histological examination, was pronounced to be an epithelioma. It was very rich in cells, but there was not much connective tissue. The cells were distributed in masses in the cavities. At the periphery of these masses the cells were clearly cylindrical, while in the center they were of various shapes according to the pressure which was exerted upon them.—*Bulletins et Mémoires de la Société Anatomique de Paris*, October, 1905.

Sections of Liver and of Spleen from a Case of Biliary Melanoderma with Splenomegaly.—Gandy recently exhibited to the Anatomical Society very interesting sections of the liver and the spleen taken from a patient whose death was due to biliary melanoderma of the Addisonian type with splenomegaly. The liver showed lesions characteristic of old biliary cirrhosis which was in the course of evolution. Here and there were numerous embryonic islands. The lesions of the spleen were especially abnormal. This organ weighed 880 grams instead of 200, the normal weight. On section, there were noted in the midst of the ordinary sclerosis of splenic pulp several nodules of a fibrocaseous aspect. Under the microscope these masses of tissue were found to be pigmented from a hemorrhagic infiltration beginning in the sheath of the follicular arterioles which were otherwise intact. There were no characteristics of tuberculous or syphilitic lesions, nor any due to infarcts. There was nothing abnormal about the suprarenal capsules.—*Le Bulletin Médical*, January 17, 1906.

A Case of Lichen Planus of Unusual Extent.—J. Nicolas and M. Favre have carefully observed this case. Its special interest had to do with the unusual extent of the lesion and its abnormal aspect, especially on the mucous membrane. The face and the scalp were the only parts intact. On the mucous membranes the lesions were confluent to a degree rarely noted in the literature of lichen. Otherwise, they were perfectly typical. Under appropriate treatment the affection was subsiding at the time of writing, and a good prognosis was given. Treatment consisted of the internal administration of arsenic, while the application of oil of cade was made to the lesions. Prolonged lukewarm douches under feeble pressure were also given.—*Lyon Médical*, January 14, 1906.

The Leucocytes in Malaria.—Giuseppe Valerio says that in malarial fever there is a marked increase of mononucleated lymphocytes, while the polynucleated remained unchanged. The author studied the effects of quinine in therapeutic doses on those phenomena, and formulates the following conclusions: The curve of the blood corpuscles shows a rhythmic rise in relation to the accessions of fever, which is probably of vasomotor nature. The use of quinine produces a sensible diminution in the percentage of white blood corpuscles. In an untreated case of tertian malaria there is a mononucleosis which is most marked at the height of the paroxysm of fever, while the number of polynucleated cells is below normal. This condition is inverted by quinine, under which there is an increase of polynucleated cells and a lessening of mononucleated ones.—*Giornale Medico del Regio Escrcito*, December, 1905.

Elimination of Uric Acid and Alloxuric Bodies by the Feees.—Carlo Bartoletti gives the results of his examinations of the feces of man in a normal condition, in gout, and in leukemia, thus: Uric acid is constantly found in the feces under normal conditions; alloxuric bodies are in relation to the quantity of the feces, not varying with the kind of food. In gouty patients there is a lessened elimination of uric acid, in leukemic conditions, an increase. The uric acid in the intestine is probably a product of the elimination by the digestive tube. The intestinal mucosa is of importance in the elimination of uric acid from the system. We may hope for new knowledge on the subject of the treatment of some pathological conditions by pursuing these researches.—*Ricista Critica di Clinica Medica*, December 16 and 23, 1905.

Is there a Special Red Blood Corpuscle in the Blood in Dementia Præcox?—Giuseppe Muggia has examined the blood of a variety of patients, including those affected by dementia præcox, epilepsy, paralysis, etc., in order to demonstrate whether, as was asserted by some authors, the blood corpuscles in the demented differed in staining characteristics from those of normal persons in such a way as to aid in the diagnosis of the condition. The author gives it as his conclusion that there is no difference of staining reaction between the normal blood corpuscles and those of the victim of dementia præcox, or other mental diseases. The differences in staining of the corpuscles is purely accidental.—*La Riforma Medica*, January 6, 1906.

The Causation and Treatment of Chronic Jaundice.—H. W. Syers defines chronic jaundice as a condition of persistent jaundice in which the symptom has been present for some time. This period is not arbitrarily fixed but it certainly lasts for six weeks or two months. The deep olive-green tint of skin so often noted in cases of persistent jaundice is not always observed. This affection may persist for long periods with no impairment of the characteristic bright yellow tint. In cases of chronic jaundice in which the gall-bladder is felt to be distended, especially at a comparatively early stage of the disease, there is considerable probability that the lesion is malignant. However, absence of obvious dilatation of the gall-bladder is perfectly compatible with the existence of malignant disease. The physical sign is very important as a positive indication, but its absence does not exclude carcinoma. Altogether apart from the presence of suppuration, rise of temperature, hectic in type, often occurs in malignant disease. Temperature must not be relied upon as an aid in diagnosis. The older the patient, the greater is the probability of an unfavorable diagnosis; nevertheless, malignant growths are observed in the young; and recently in a man seventy years old who was observed by the writer, chronic jaundice persisted for over a year and a half, together with wasting and loss of strength. This case was one of obstructon by gallstones with dilatation of the ducts. Increase in size of the whole liver, unless this change is rapid and uneven, is an unsatisfactory sign in relation to diagnosis. Treatment of chronic jaundice is absolutely unsatisfactory. The writer believes that the olive-oil treatment is powerless to relieve. In a large number of cases the only treatment left is the adoption of surgical methods, but the writer believes that there should be considerable hesitation before resorting to operation.—*Treatment*.

Book Reviews.

Physical Diagnosis, Including Diseases of the Thoracic and Abdominal Organs. A Manual for Students and Physicians. By Egbert Le Fevre, M.D., Professor of Clinical Medicine and Associate Professor of Therapeutics in the University and Bellevue Hospital Medical College; Attending Physician to the Bellevue and St. Luke's Hospitals, etc. Second Edition, Thoroughly Revised and Enlarged. Illustrated with 102 Engravings and 16 plates. Philadelphia and New York: Lea Brothers & Co., 1906.

While there has of late been no dearth of excellent new books dealing with this subject, some of them originating in this country and others appearing as English translations of foreign works, Dr. Le Fevre's manual seems to have secured a prominent place among them. This is hardly surprising, for the author has understood very well how the "insistent why" of the students he refers to in his dedication must be answered, and has given extremely clear and convincing explanations of the physical reasons underlying the auscultatory and other signs present in various phases of disease. This feature alone is sufficient to render the volume of especial value to the student, who, as the author says, is only too likely "to regard each variation from normal as pathognomonic of special disease rather than as dependent on changes in structure or function which may be present in conditions not necessarily pathological." The text of the present edition has been somewhat amplified in order to bring the book into accord with the modern tendency of teaching physical diagnosis at an early period in the curricula of the medical schools, and the number of illustrations has also been increased. The reproductions of skiagraphs of the chest are especially interesting and instructive. Only one inaccuracy of moment has caught the reviewer's eye, and that is the transposition of the two German words *Klingend* and *Klanglos* in the schema of graphic records of physical signs, with a resulting reversal of meaning. The popularity of the book shows that it appeals to the student's mind and it certainly possesses the virtues of clearness, comprehensiveness, and suitability for pedagogic purposes.

Life and Matter. A Criticism of Professor Haeckel's "Riddle of the Universe." By Sir Oliver Lodge. New York and London: G. P. Putnam's Sons. 1905.

Sir Oliver Lodge attacks the philosophy of Haeckel, particularly as expressed in the volume mentioned on the title page, with a degree of acerbity justified only by the eminence of the assailant. He especially deplores, he says, the fact that an English translation of the German scientist's work has obtained a wide circulation among the artisan class of England, being purchasable for sixpence at any bookstall, and the present volume is intended to counteract the erroneous conclusions as to facts and deductions into which its readers may be led. The chapter headings are as follows: Monism; The Law of Substance; The Development of Life; Memoranda for Would-Be Materialists; Religion and Philosophy; Mind and Matter; Professor Haeckel's Conjectural Philosophy; Hypothesis and Analogies Concerning Life; Will and Guidance; Further Speculation as to the Origin and Nature of Life. The author's opinion of Haeckel and his work may be derived from this extract taken from page 51: "He (Haeckel) is as it were, a surviving voice from the middle of the nineteenth century; he represents in clear and eloquent fashion, opinions which then were prevalent among many leaders of thought—opinions, which they themselves, in many cases, and their successors still more, lived to outgrow; so that by this time Professor Haeckel's voice is as the voice of one crying in the wilderness, not as the pioneer or vanguard of an advancing army, but as the despairing shout of a standard bearer, still bold and unflinching, but abandoned by the retreating ranks of his comrades as they march to new orders in a fresh and more idealistic direction." On page 168 he explains his attitude of antagonism by saying: "My chief objection to Professor Haeckel's literary work is that he is dogmatic . . . and would have people believe, what doubtless he believes himself, that he already knows the answer to a number of questions in the realms of physical nature and of philosophy. He writes in so forcible and positive and determined a fashion, from the vantage-ground of scientific knowledge, that he exerts an undue influence on the uncultured among his readers, and causes them to fancy that only benighted fools or credulous dupes can really disagree with the historical criticisms, the speculative opinions and philosophical, or perhaps unphilosophical, conjectures thus powerfully set forth." The author's eloquence of style, which is not, however, wholly free from the positivism for which he criticises Haeckel, and the evident sincerity of his convictions render the little volume an interesting exposition of the views of one of the most prominent scientific investigators of the day.

Spemanns Historischer Medicinal-Kallnder. 1906. Bearbeitet von Prof. Dr. J. Pagel und Prof. Dr. J Schwalbe, in Berlin. New York: Paul B. Hoeber, 1906.

This attractive calendar presents on each leaf either the portrait of some medical celebrity whose career is associated with that day, or a reproduction of some old print or etching having reference to medical subjects. Data regarding the birth and death of eminent medical men, and references to anniversaries in the history of medicine are also provided in great profusion. Sufficient space for memoranda is left on each sheet, so that the calendar should be both useful and interesting for German physicians.

Sea Shore Life. The Invertebrates of the New York Coast and the Adjacent Coast Region. By Alfred Goldsborough Mayer, Director of the Marine Biological Laboratory of the Carnegie Institution at Tortugas, Florida. New York: A. S. Barnes & Company, 1906.

The author of this charming little book has presented it as a gift to the New York Zoological Society, and the proceeds from its sale are devoted to the improvement of the Aquarium. It is the first of a series to be issued under the auspices of the Aquarium and intended to be written in simple fashion so as to be interesting to the layman, while, at the same time the standing of the authors will lend authoritativeness to the volumes. In the present instance this combination of qualities has been most successfully attained and we trust that a wide circle of readers will enjoy the excellent description and interesting photographs of the North Atlantic invertebrates which the author has prepared. The figures are nearly all reproductions of photographs by the author and bear witness to his technical skill in this direction as well as in the literary art. Even those who dwell far away from the shore may derive pleasure and profit from this attractive book.

Le Poignet et les Accidents du Travail. Étude radiographique et clinique. Par le Docteur Destot, Chef de Laboratoire de Radiographie des Hôpitaux de Lyon. Paris: Vigot Frères, 1905.

Destot presents a study of the mechanism of injuries to the bones of the wrist in its relation to accidents incidental to occupations. He aims to show the importance of the first row of the carpus in fractures and dislocations of the wrist, with the aid of radiographic studies directed especially to the physiology of the movements of the wrist bones and the statics and dynamics of wrist injuries. Destot furthermore attempts to give a summary of the diagnostic features of these injuries and of the numerous sources of error encountered by the accident expert. It is a pity that the illustrations—rough pen sketches—are beneath criticism. Not a single radiograph is reproduced of the hundreds taken by the author of this little monograph.

Lectures on Autointoxication in Disease, or Self-Poisoning of the Individual. By Ch. Bouchard, Professor of Pathology and Therapeutics; Member of the Academy of Medicine and Physician to the Hospitals, Paris. Translated, with a Preface and New Chapters added, by Thomas Oliver, M.A., M.D., F.R.C.P., Professor of Physiology, University of Durham; Physician to the Royal Infirmary, New Castle-upon-Tyne; Formerly Examiner of Medicine, Royal College of Physicians, London. Philadelphia: F. A. Davis Company, 1905.

It is twelve years since the first edition of this translation of Bouchard's Lectures on Autointoxication in Disease appeared. Unfortunately Professor Bouchard has not been able to rewrite or revise his original work, and consequently this second edition does not represent anything new from the pen of the distinguished author. But the translation has been revised and the subject has been brought up to date by several valuable additions on the part of the translator. Almost every chapter contains new paragraphs thus added by Dr. Oliver. Among the more important of these additions are sections on the toxemia of pregnancy; criticism of Bouchard's views on urinary toxicity; Kukula's experiments on intestinal obstruction; the views of Hoppe-Seyler and of Herter on intestinal toxins; Chambrelent and Bois' researches on the toxicity of the urine during pregnancy; the toxicity of indol; constipation; toxemia as a possible cause of asthma; gastric tetany and the experiments of Halliburton and McKendrick and of Bouveret and Devic; and cholera and its treatment. This new addition also contains an appendix of two chapters written by Dr. Oliver, one on the Natural Defenses of the Organism against Disease; and the other on Autointoxication of Intestinal Origin. The book as it now stands contains an able and up-to-date account of an important subject; and the reader will find in it not only a translation of Bouchard's work, but also considerable criticism of some of his theories; at the same time there is no lack of mention of the labors of many other workers in this interesting field of study. We are indebted to Dr. Oliver for a work which appeals to and should be read by every physician and student

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

Regular Meeting Held January 4, 1906.

DR. CHARLES L. DANA IN THE CHAIR.

Reading of Annual Reports.—These reports were read by the secretary and ordered placed on file.

Some Recent Advances in Cardiac Pathology.—Dr. C. N. B. CAMAC presented this communication. He first referred to the last number of the the *Journal of Experimental Medicine*, in which appeared an article by Joseph Erlanger. This article (the first of a series) was an exhaustive report upon Adams-Stokes' disease and the production of "heart-block" in the dog. He said that His, Jr., had demonstrated in 1893 that the only connection between auricle and ventricle was a small strip of muscle situated in the auriculoventricular septum. This auriculoventricular bundle, or bridge, lay at the base of the middle leaflet of the tricuspid valve, where it most nearly approached the membranous septum and terminated at the root of the aorta. The length of this strip was 18 mm., the breadth was 2.5 mm., the depth, 1.5 mm. The muscular structure of the auricle was in a continuous ∞ shape, as was also that of the ventricle, the cavities of the heart being contained within the hollows of the ∞. The bundle of His was the sole connection between the auricles and ventricles. In 1904 His suggested that the bradycardia, epilepsy, pseudoapoplexy, etc., associated with Adams-Stokes' disease (first described by Adams, 1826, and subsequently by Stokes, 1846,) was due to a lesion in this bundle. He explained these phenomena on the theory that "heart block" occurred. Heart block was a condition in which the auricle beat at a different rate from that of the ventricle, and was first produced by Stannius in 1856 by placing a ligature about the auriculoventricular groove in the heart of a cold-blooded animal. Stannius was unable to account for this phenomenon which His assumed was the result of compression of the auriculoventricular bundle, the only means by which the impulse originating at the base of the heart could pass from the auricles to the ventricles. The ventricles thus freed from the auricles (their normal pace maker) beat at their own inherent slow rate, and thus resulted pulsations in the jugular two, three and four times more frequently than those of the radial artery, a clinical observation first made by Stokes in 1846. Erlanger in 1904, working in the Physiological Laboratory of the Johns Hopkins University, was able by means of a special devised clamp to compress this muscular bundle in the dog, and at will produce a half, third, and a quarter rhythm, and finally the complete block, *i.e.* the ventricle at a standstill while the auricles continued to beat. A series of experiments was carried out with different drugs which influenced the heart muscle, the sympathetic, and the pneumogastric nerves, and it was shown conclusively that the seat of trouble in the Adams-Stokes syndrome was in this auriculoventricular bundle. The significance of these observations was at once appreciated. They were not only confined to the Adams-Stokes syndrome, but extended as well to any condition which involved this muscular band as fatty, sclerotic, or circulatory changes, and influences exerted by variations in sodium and calcium composition of the circulating stream (Loeb, Howell, *et al.*) Dr. Camac gave a summary of the more important of the accepted physiological teachings with regard to the cardiac ganglia and inherent rhythm of the heart muscle (Weber, Engleman, Caskell, *et al.*) and their bearing upon "heart block." The ganglia had no power to originate impulses but acted as transmitting stations. The heart began to beat rhythmically in the embryo before it contained any nerves. He showed a specimen in which this muscular bundle had been tied off and dissected out. He also showed a specimen from a case of bradycardia with pseudoapoplectic seizures. The number of beats in this case dropped to 30 per minute. The aortic valve was much involved. The association of bradycardia and pseudoapoplectic seizures and involvement of the aortic valve deep down into the tissues were the significant features. The points for clinicians to watch for in contributing to this important subject were: (1) Bradycardia, paroxysmal or continuous; (2) pseudoapoplectiform and epileptic attacks with slowing of the pulse; (3) a jugular pulse beating at a different rate from that of the radial; (4) preservation of the uncut heart in case of death, until one familiar with the sectioning of this muscle bundle could be procured to make such a section.

The Treatment of Chronic Diseases of the Heart by the Nauheim Methods.—Dr. FRANCIS P. KINNICUTT read this paper, largely based upon his personal study of the treatment at Nauheim in the summer of 1904 and again in 1905. Every facility for this purpose was afforded him by Professors Schott, Heineman, and Groedel. The composition of the Nauheim waters and the technique of the baths and Schott "resistance exercises," the combination of which constituted the Nauheim treatment, were fully described. Dr. Kinnicutt then considered the physiological action of both the baths and the exercises, which established a scientific basis for their use. The subject was then taken up from the clinical standpoint and the therapeutic value of the treatment in the different forms and degrees of cardiac inadequacy were discussed. Finally, the speaker formulated these different forms in the order of benefit to be expected from the treatment, and gave the general contraindications for its employment, as well as the indications for the modification of the baths and the exercises in cases in which they were applicable. He was very positive in his opinion of the therapeutic value of the Nauheim methods, but insisted upon the necessity for much discrimination and care in their use, as they could be potent for harm as well as good.

Dr. GEORGE L. PEABODY said that in 1898 he spent five weeks at Nauheim and was then impressed with the fact that no two of the numerous physicians applying their treatment did so in the same way; the treatment then obviously was in the experimental stage. He also was greatly impressed with the willingness on the part of the patients to place themselves at his disposal as clinical material, and all seemed willing to aid him in his studies, allowing themselves to be examined before and after treatment. He was more impressed with the general results than the immediate effects. Many forms of cardiac inadequacy were much benefited by the treatment, and many of these people had been there for many successive seasons with the net results that good had resulted. As to the physiological explanation of the effects produced, opinions were still somewhat at variance, but he believed the following to be true. Hot baths caused an increase in the frequency of the pulse and dilatation of the peripheral blood-vessels, followed by decrease in pulse rate and lowered blood-pressure with improvement of heart tone. Cold baths contracted the peripheral blood-vessels, increased the blood-pressure, and lessened the frequency of the pulse. The mineral baths caused a mechanical irritation of the sensory nerves of the skin, and when carbonic acid gas was added the stimulation of the peripheral tissues was obvious. When a thermal irritation was added the presence of these chemical ingredients seemed to be able to cause a more persistent arterial flux to the skin, with dilatation of the peripheral blood-vessels, diminution of the pulse about 10 or 20 beats, and an increase in the blood pressure. Whereas, if ordinary water were used at the same temperature the pressure was likely to be somewhat lowered. Dr. Peabody said that too much should not be expected of the baths. In a general way they were not good in advanced cases of cardiac insufficiency. When we could hope to improve the bodily tone and strength of the patient, as in the beginning of failure of compensation with valvular disease, or early in the failure of the heart power with valvular disease, then they might be of value. Massage in a centripetal direction at the beginning of the baths at Nauheim had its influence in assisting the discharge of blood from the veins.

Dr. WILLIAM H. THOMSON related an interesting experi-

ence he had had. A man who appeared to be an ordinary laboring man came to his office and stated that he had been recommended to come to New York to consult some doctor regarding his heart. No cardiac impulse could be found, and the heart was extremely irregular in both frequency and volume, indicating that the organ had difficulty in emptying itself. He was puzzled to account for the amount of dilatation without concomitant symptoms. The arteries all over the body were healthy and compressible. There was no emphysema of the lungs. The urine was normal. He learned that the man's business was copper mining, at which he had been engaged for thirty years in Montana at an elevation of 7,000 feet. Arsenic was present like "hoar frost." Dr. Thomson concluded that he had a fatty degeneration of the heart from chronic arsenical poisoning, with dilatation because of working at an elevation of 7,000 feet. He had to go up and down ladders twenty times a day. One year later Dr. Thomson was called again to see the man at his hotel. He found him with orthopnea and in bad condition. After eight weeks he was able to go about his business. Dr Thomson overheard a remark about Nauheim and he told the patient that if he went there it would kill him. He lost sight of him for two months, when he was again sent for and found him suffering from general anasarca, etc., and two months later he died with secondary involvement of the kidneys. This patient had received 52 Nauheim baths. Dr. Thomson said that Nauheim physicians had requested that patients suffering from fatty degeneration of the heart should not be sent there.

Dr. Thomas E. Satterthwaite said that the inharmonious action of the auricles and ventricles in the Adams-Stokes syndrome might be functional. In a characteristic case where the patient was unconscious for more than a week the symptoms disappeared and he regained his former health. The lesions in such cases was some temporary disturbance in the cranial cavity. He had been practising the Nauheim treatment for nine years, and had prescribed thousands of baths, and thousands of exercises. The heart actually shrank under both baths and exercises, but not in all cases; sometimes the organ was so infiltrated with fibroid tissue, or bound down by adhesions in pericarditis, that it could not shrink. Of the conditions most benefited by this treatment, he would put the neurotic before the organic, placing angina pectoris in the neurotic class, as he held that it was almost always a functional disorder. The Nauheim treatment was intended mainly for cardiac irregularity or inadequacy. Of organic diseases it was particularly well suited for the dilatation of mitral insufficiency. Acute endocarditis, advanced tuberculosis of the lungs, and chronic parenchymatous nephritis were absolutely contraindicated. Personally he did not know of any mishap or bad result from the artificial baths. He had, however, seen a case in consultation, where an artificial bath, after a recovery from acute nephritis, had apparently precipitated a return of the disease, with a fatal result. In this country we were disposed to be more conservative than on the other side of the water, he believed. He employed it in only about 30 per cent. of his cardiac cases; in the balance it was contraindicated or impracticable, for various reasons. Views as to the advantages of general massage had altered of late. He never allowed any general massage of the abdominal region, because of its possible reflex action on the heart, if applied with much force. Direct massage of the heart was useful; it contracted the heart, as had been shown by Abrahams of California. But the physician alone should employ it.

Dr. Charles E. Quimby said that for fifteen years he had been treating cardiac cases differently, and his results had been such that he did not feel warranted in giving up his own treatment for the Nauheim.

Dr. A. Jacobi said that we had a great many heart remedies and the Nauheim treatment was to be classed as one of them. He spoke of the great difficulty in making a diagnosis in these cases, and by diagnosis he did not simply mean recognizing a murmur. All knew how difficult it was to make a diagnosis and to recognize the efficacy or absence of efficacy of remedies. He asked if Nauheim used other remedies. All were inclined to use one remedy for one thing, and this amounted almost to a fad. Sometimes one gave up well-established treatments for some new treatment and, therefore, he inquired if at Nauheim they used remedies besides the Nauheim treatment. While Nauheim was being eulogized he would not care to rely upon it unless careful attention was also paid to the well-established forms of treatment, particularly that which aimed at the relief of the heart muscle.

Dr. Kinnicutt said that the physicians at Nauheim were judicious in carrying out the treatment and that other treatment besides the Nauheim was used when it was thought advisable. Many patients came to Nauheim who were taking drugs, and these were not discontinued. The desire of these physicians was to get along without them if they could; but so far as his observation went they never omitted anything that was productive of good.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON PEDIATRICS.

Stated Meeting, Held October 12, 1905.

Dr. L. E. LaFetra in the Chair.

A Case of Acrondroplasia.—Dr. Henry Heiman presented this patient. A male infant, six months of age, was admitted to Mount Sinai Hospital in June, 1905, because of a genital abnormality which the mother desired corrected by operation. After operative procedure for hypoplasia of the penile structures the child was transferred to the medical service for observation. There was no history of dwarfism in the family. An older child, two years of age, was normal in intelligence and appearance. The previous history of the case was negative. The urine had always been voided from a small, round orifice, situated in the usual site of the penis. This opening was on a level with the surrounding skin, and underneath could be felt a small penile body about one-quarter of an inch long. When the lips of the orifice were everted there were disclosed the prepuce and glans of a diminutive penis. The left testis was in the scrotum, while on the right side was a hydrocele and a congenital hernia. The operation had resulted in no decided improvement in the appearance and position of the parts. The patient seemed to be well nourished and in good general condition. The facial expression was almost imbecile, the voice seemed to be normal, and the infant seemed to be able to see and hear. The head was about normal in size, but rachitic in shape, the bosses were prominent, the anterior fontanelle wide open, and the posterior closed. The hair was sparse and absent from the occiput, but otherwise normal. The ears were considerably deformed and the eyes negative. The nose was short, flat, and retroussé, the bridge short and depressed, the nostrils wide and directed forward rather than downward. The gums were enormously hypertrophic, irregularly thickened, showing elevations and depressions seemingly corresponding with the sockets of teeth. The gingival tissue was redundant throughout the whole extent of the upper and lower alveolar borders. The hard palate was high arched; the soft palate was thickened and extended almost to the posterior pharyngeal wall. The neck was short. There was no enlargement of the lymph nodes. There was normal thymic percussion dullness. There was eczematous eruption on the face and trunk. The conformation of the chest wall was normal. The abdomen was protuberant, the anus relaxed, and the rectum not prolapsed. The extremities were short, the bones curved and thickened. The soft tissue of the forearms and legs was markedly redundant. The motions of the joints seemed to be abnormally free. The hands were flat and showed the trident deformity. The third toe on both sides was diminutive, deformed, and without a nail. Most of the nails were ill developed. Subnormal temperature was frequently present. The weight

varied from ten and one half to thirteen pounds. The urine was negative. The hemoglobin percentage was about 35.

A Case of Cretinism.—Dr. HENRY HEIMAN also presented a case of cretinism which had shown rapid improvement under treatment with thyroid extract. This patient came under observation last February, when seventeen months of age. There was no family history of idiocy, consanguinity, or other possible etiological factor. Two older children were healthy and intelligent. At six months of age the child had pertussis. Later the abdomen began to enlarge and the child did not seem as bright as other children. At the age of one year the baby looked stupid, was unable to support its head, slept nearly all the time, and constantly protruded its tongue. The usual thyroid treatment was started and had been continued to the present time. In February, 1905, the child showed the characteristic symptoms of cretinism, while at the present time there were evidences of intelligence. The facial expression was bright. The skin had become smooth and soft, the hair abundant and fine, though the kyphosis remained unchanged. The head could be held upright. The macroglossia was still present, though infrequent and slight. At the age of seventeen months the child weighed 15½ pounds and measured 60 cm., while it now weighed 19 pounds, 2 ounces, and measured 71 cm. The abdomen was not abnormally prominent at the present time. The hernia was no longer present. The temperature was now normal.

A Case of Dwarfism.—Dr. FREDERICK L. WACHENHEIM reported this case. The patient was presented for some deformities which might lead one to think of dystrophy. The child was three and a half years old, with normal intelligence. There were a number of other children in the family showing conditions somewhat similar. The head was typically a rachitic one, and the face appeared rachitic. There was a depression of the nose and the palate was flat. There was a flattening of the thorax, and the arms showed thickenings at the epiphyseal ends. The most remarkable thing regarding the case was the condition of the legs. Both femora were short—the result green stick fractures. The tibia showed this deformity to a particularly high degree. The chief point of interest was the shortening of the femora. Attention had not been called to this condition, nor, in fact, had it been noted that these green-stick fractures had occurred. Two photographs of the patient were shown. There was a remarkably good demonstration of the rachitic hand.

Dr. CHARLES HERMAN, in discussing Dr. Heiman's first case, said that the marked curvature was not opposed to such a diagnosis as was made. He had seen cases of rickets in which the curvatures were even more marked than in this instance. He thought that the case of chondrodystrophy presented points which were not typical. The case was atypical with reference to the lower extremities. He could not recall any case of chondrodystrophy in which the condition was confined solely to the upper extremities.

Dr. NATHAN said that the fact that the lower extremity was shorter would not militate against the condition being one of chondrodystrophy. The upper extremities were quite characteristic. Dr. Nathan said that he had seen thousands of cases of rickets, but never one deformed to the extent of the case presented. The case would remind one of osteogenesis imperfecta. He thought the use of the *x*-ray would be useful in determining the condition and density of the bone. The condition in rickets was very different from that in osteogenesis imperfecta.

A Case of Congenital Syphilis with Bone Lesions.—Dr. NATHAN presented a young girl who came to him two years and a half ago with a swelling of the ankle, which looked like a tubercular arthritis. No history of syphilis was obtainable. A few months after he noticed that the condition was not localized, but extended along the tibia. In syphilis there would be a periosteitis and swelling of the bone in the region of the joint. Later on a gumma broke down, not into the joint, but externally. Tubercular foci break into the joint. He had placed the girl on antisyphilitic treatment and she recovered rapidly. Recently more characteristic lesions of syphilis were noted along the tibia, namely, the osteophytes. He found that this was due to a central gumma. The condition in this case was monoarticular.

A Case of Malaria, with Cerebrospinal Symptoms.—Dr. M. NICOLL, JR., presented this case. The patient was a boy, five and one-half years of age, the son of a United States Army surgeon. He had a history of severe bronchopneumonia in infancy, and a severe obscure illness of six weeks' duration in Cuba, which, it was thought, might possibly have been malaria of a remittent type, but the plasmodium was not found and quinine was not effectual. In July of this year he received a slight wound of the foot while wading in salt water. Two days later he was drowsy, slept restlessly, and complained of the back of his neck. His temperature was 102°. Fearing tetanus, the wound was opened and treated as though it were infected. Later in the day the head was retracted to a marked degree. The sternocleidomastoid muscle was tense. The head could not be sent forward with any justifiable degree of force, and attempts to do so caused pain referred to the back of the neck. A few hours later there were symptoms of approaching convulsions. A supply of antitoxin was sent for. The urine at this time was negative, the fresh blood showed plasmodia of a hyaline type, and consequently bimuriate of quinine was given between 5 P. M. and morning, when a second blood examination showed the same type of organism. During the next twenty-four hours eighteen grains of quinine were given. The patient made a rapid recovery. He had reported this case because he had not seen, nor been able to find recorded, a case so suggestive of involvement of the brain and spinal cord caused by malaria.

Dr. WILLIAM B. NOYES said that he had seen a similar case at the Columbus Hospital in 1895. A man fifty years of age was found lying in coma with stertorous breathing. Uremia and cerebral hemorrhage not giving localized symptoms were thought of. Before the patient died the blood was examined and found to be filled with pigment. At the autopsy no lesions were found except congestion of the brain. The sections of different parts of the brain showed a beautiful stain. The patient died from pernicious malarial fever. The pigment seemed to be more responsible for the general state of coma than anything else.

Dr. HENRY HEIMAN said that a patient was brought to Roosevelt Hospital with symptoms similar to those of the patient presented by Dr. Nicoll. The capillaries of the brain contained numerous parasites of pernicious type, *i.e.* crescentic. These types were rarely seen north of the Mason and Dixon line. Only a few cases were on record. He was inclined to believe that in the cases cited the parasites had been imported from Cuba, and had been lying dormant.

Dr. JACOB SOBEL said that possibly they might have been dealing with that grave form of tetany which was associated with opisthotonos, and asked Dr. Nicoll if Trousseau's phenomenon was present.

Dr. L. E. LAFETRA said that in connection with the cerebral types of malaria there were two other features which should be borne in mind: (1) those cases with marked respiratory symptoms and (2) those with cardiac symptoms. In the first there were symptoms simulating those of pneumonia. There was marked congestion of the lungs with the capillaries filled with the parasites, as they were in those cases with cerebral symptoms, where the capillaries of the brain had them in abundance. In the cardiac cases there was rapidity of the pulse, dyspnea, and prostration. He cited the case of a child where the question arose whether there was some serious heart trouble. The child was known to have some congenital lesion, and it was thought that fever had produced some change in the heart's action, and perhaps dilatation. Blood examination revealed the malarial parasite, and treatment with quinine quickly cleared up the dyspnea.

Dr. Nicoll said that Trousseau's symptom referred to was not elicited. The patient had not been out of Cuba more than nine or ten months, and he was inclined to think that the organism had been lying dormant in the system.

Myotonia Congenita or Thomsen's Disease.—Dr. Frank S. Meara referred to a treatise on organic nervous diseases in which Starr, writing in 1903, stated that but thirty cases had been recorded in the literature up to that time, and that the affection might, therefore, be considered rather a curiosity. A case was then cited by Dr. Meara that fitted so precisely to Thomsen's description that he deemed it worthy to be added to the published list. The case met with all the criteria of Thomsen's disease. It was a congenital affection of the muscles, characterized by a stiffness accompanying the initiation of every muscular movement, which passed off on continuance of the effort, and a peculiar change in the muscles in response to electrical or mechanical excitation.

Dr. James Ramsey Hunt said that he believed there were more cases on record than were given by the statistics quoted from Starr. He recalled a thesis in which one hundred cases were reported, and in the original theme of Thomsen twelve or fourteen cases were recorded. The pathology of the affection was very obscure. Some believed in the intoxication theory. Since the description of myotonia congenita the affection had assumed a much wider interest, and seemed to be associated with a great many other affections of the nervous system. Myotonias might come on in middle or early adult life. In his own work he had seen two cases within the last five years. One of these cases was of the acquired form coming on at the age of twenty-five years. It was confined to the muscles of deglutition, mastication, and of the hand, and was more or less stationary. No abnormal constituents were found in the urine. The other case was interesting because of the localization. The patient was a young girl, fourteen years of age, and there was a partial myotonic condition. This was difficult to bring in with the theory of autointoxication. There were groups of cases associated with atrophy instead of hypertrophy. Some atrophies were central in origin and some secondary to the myotonia. In speaking of myotonia, he thought it was always wise to speak of the allied condition which was called paramyotonia, which came on in otherwise healthy individuals after exposure to cold, etc. Cases had been described in which the symptoms of myotonia, with well marked electric reactions, had been associated with paramyotonias. There seemed to be some relationship between the two. Paramyotonia was supposed to be due to vascular spasm, producing an angiocontraction or angioconstriction of the blood vessels with resulting ischemia of the muscles.

Dr. Schwarz called attention to a form of myotonia occurring in infants under six months of age associated with gastroenteritis and congenital syphilis. There were two forms, one Erb's, with increased galvanic irritability, and the other accompanied by balling of the fist. Trousseau's sign was not present. It was distinguished from tetany in that one did not meet with the general phenomena of laryngismus stridulus, or continued spasm of the muscles.

The Etiology of Noma.—Dr. Charles Herman presented this paper. After reviewing the work of investigators on this subject, and describing his own work in detail, he said that, although absolute certainty was impossible until pure, uncontaminated cultures and successful inoculations in animals could be obtained, the following conclusions might be drawn with a fair degree of probability: 1. The microorganism which he called the spirochete of necrosis, corresponding to the streptothrix of Schiffert-Perthes, was the one which played the most important part in the etiology of noma. 2. This organism was identical with that found by Plant, Bernheim, Vincent, and others in the ulceromembranous lesions of the mouth, and, also, 3. with the *Spirillum sputigenum* and *Spirochæta dentium* of Millee, found normally in small numbers in the mouth. 4. Though apparently two organisms they were really different parts, or different stages of development, of the same organism. 5. This microorganism was not a bacillus, but probably belonged to a family which served as a connecting link between the bacteria and the protozoa, namely, to the family of *spirochætæ*. This explained why it could not be stained and grown on culture media by the usual methods. 7. This organism was probably present in the atmosphere in the form of very resistant spores. When deposited on food, water, milk, directly or indirectly, it might be introduced into the body with these. 8. It was closely related to *Bacillus necroseos* found in the necrotic processes observed in some of the lower animals. 9. In the human body this organism required unusual and exceptionally favorable conditions for its growth and development. On this account noma was very slightly contagious. In order that a gangrenous process should result, there must be a preceding physiological change in the tissue, which rendered it possible for the organism to penetrate, live, and multiply in the apparently healthy portions. 10. Ulcerative and gangrenous stomatitis represented different stages of the same process. 11. The presence of diseased teeth undoubtedly played an important part in the etiology of ulcerative and gangrenous stomatitis, partly by pressure and irritation, but primarily by producing a gingivitis, furnishing conditions favorable for the growth and development of the organism described, the space between tooth and gum furnishing a storehouse for fresh supplies. 12. In the infectious diseases of childhood particular attention should be paid to the condition of the teeth. When diseased they should be removed. 13. The most rational treatment of noma was the application of the Paquelin cautery. It should be introduced so as to destroy, not only the necrotic tissue, but also the finer filaments of the microorganism which have penetrated into the underlying apparently healthy tissue. 14. The term noma was here used to indicate a specific necrotic process. Similar processes might occur in any part of the body, providing always that certain physiological changes have taken place in the tissues, which rendered it possible for the microorganism to penetrate, live, and multiply in the apparently healthy parts.

Dr. Howard Lilienthal said that, considering the enormous number of poorly nourished children who were affected with the exanthemata, and who presumably had the spirocheta in their mouths, he thought it quite remarkable noma was such a rare sequella. He said that he could not understand why burning out the disease with the cautery should check its course. This proceeding did not change the condition of the patient, but only removed the affecting organisms. He was quite sure it was not necessary to kill all the bacilli, as in tuberculosis. A few months ago Dr. Koplik had transferred a child to Bellevue, refusing to operate because the disease was so contagious. Dr. Lilienthal said this was a surprise to him. He had been unable to find anyone who would say that the disease had spread in any ward in which it had been treated, yet all agreed that the affection was very offensive, and tried to get rid of treating it. It seemed to him that the sooner a child was operated upon, the better the chances of recovery. He believed that if noma was due to any specific organism in the mouth, wounds and operations in the mouth would show signs of infection, yet such wounds healed with great promptness because of the great blood supply.

Dr. Jacob Sobel said that during the past ten years he had seen three patients, all of whom had died. He did not believe that all cases of gangrenous stomatitis were due to one and the same organism. He could not understand why some cases should not recover while others, apparently hopeless from the beginning, should be cured. He believed the condition to be contagious, and thought such cases should be isolated. The cases of noma in which the diphtheria bacillus was found should be classed by themselves. When they were found in pure culture and antitoxin given the chances for recovery were increased. He

thought that gangrenous stomatitis was a form of moist gangrene.

Dr. J. Finley Bell of Englewood said that he had a patient last summer in the Englewood hospital who had had a frank pneumonia, and after it had resolved a sore was noticed in the mouth. The following day it had spread and he had cauterized it. The next day he was positive that he was dealing with a case of noma. The gangrene lasted four days, when the child died; the whole side of the face, from the eye down to the border of the jaw, was involved, and the affection had spread with great rapidity.

Dr. A. Mayer said that in all probability the name noma embraced more than one disease. Before the era of antitoxin it was not so uncommon to find noma following diphtheria. He had seen three or four such cases. He cited one case in which he felt sure that life had been prolonged by the use of antitoxin, and was confident that had the antitoxin been administered earlier the life of the patient might have been saved. A culture was taken which showed a mixed infection, Klebs-Loeffler with the streptococci supervening. It was in reality a streptococci infection. He said a recent method of treatment had been advocated which he thought might be of value, viz., the use of incandescent electric light through red glass, using 16 candle power.

Dr. J. L. Blumenthal recalled the case of a child fourteen months old which occurred in the Children's Hospital. The child was taken ill suddenly; in a few hours the gums became gangrenous. The gangrene spread so rapidly that the case was operated upon. To do a thorough operation several teeth were removed, and even a portion of the hard palate. In doing this the nasal cavity was exposed from the mouth, and the entire exposed surface was swabbed with nitric acid. He did not believe that the cautery would have done much good in this case, as the gangrene spread so rapidly. The case was kept in the ward with other children and no other cases developed. The child made a perfect recovery. The gingival portion grew so that four months after no one who looked at the child's face could tell that an operation had been performed. The remaining palate had continued to grow, and was completely covered in, so that it was difficult to tell where the operation had been done.

Dr. M. Nicoll, Jr., said that he had seen many cases of noma before the antitoxin treatment of diphtheria came into vogue, but since the use of antitoxin had become general, and immunizing doses were so often administered, noma had become very rare.

Dr. L. E. LaFetra said that he had been on the service at Randall's Island and could confirm all that had been said in regard to the severity of some of these cases and the satisfactory results that Dr. Bainbridge had obtained. He believed that the diphtheria bacillus was certainly the starting point of a great many cases of noma.

Dr. Herman, in closing the discussion, said that there was no reason why the diphtheria bacillus should not be found in the lesions of noma. If the antitoxin cured the diphtheria, that was all that it did cure. Noma could be found in other parts of the body. He considered that the disease was slightly contagious. He thought the cautery treatment was the best.

Stated Meeting, Held November 9, 1905.

Dr. L. E. LaFetra in the Chair.

Recent Ideas on Pathology and Etiology of Rheumatism.—Dr. David Bovaird, Jr., read this paper. He said that if we confined ourselves to the consideration of acute articular rheumatism we found that most authorities agreed that it was rare in infancy and childhood. Raucafuss found only 5 cases among 15,000 infants and Widerhofer among 70,000 had never sen a single case. The incidence of rheumatism increased with years. In England the curve of rheumatism closely corresponded with those of scarlet fever and typhoid. In Montreal and Boston, Osler found the largest number of cases in February, March, and April. There seemed to be some ground for a belief in a hereditary predisposition to rheumatism, although it would seem to play a less important part than was generally supposed. He briefly summed up the results of earlier studies on the bacteriology of acute rheumatism. According to Symes the preponderating weight of evidence was in favor of the view that the specific organism of rheumatic fever was a diplococcus which was capable of assuming a streptococcal form, and which might possibly, in the course of further involution, acquire a bacillary type. What most inclined one to accept his opinion was the fact that many observers in different countries had reported fairly concordant results. It was highly probable that the coccus found by various observers belonged to one and the same type, to which had been given the name *Diplococcus rheumaticus*. This organism measured 0.5 to 1 micron in diameter and was found in pairs or short chains, and had been isolated from the blood, urine, joint fluids, and tonsils in cases of acute rheumatism, from the valves in endocarditis, the effusion in pericarditis, and from the blood in chorea. It grew best in a medium of broth and milk acidified with lactic acid, but might be grown aerobically on blood agar, peptone agar, milk, broth, or gelatin. The diplococcus did not form gas, it stained readily by aniline dyes and was not decolorized by Gram's method. He said that his reasons for accepting this diplococcus as the specific organism in rheumatic fever were (1) its discovery by so many independent observers in the blood tissues, secretions or excretions of patients suffering from this disease, (2) its isolation in pure culture, (3) the inoculation of the organism in susceptible animals produced quite regularly arthritis, pericarditis, endocarditis, myocarditis, pleurisy, iritis, and chorea. He thought that while the chain of evidence might not be quite complete we might accept the proposition that rheumatic fever was an acute infectious disease and that the specific organism was known. The disease was suggestively like other acute infectious diseases. This theory of the etiology of rheumatism was far more rational than the old one. As we thus far knew nothing of the manner of infection beyond the fact that the organism had been found in the tissues of the throats of those suffering from rheumatic fever called to mind the emphasis that Packard and others had laid on the close relationship between attacks of tonsillitis and the outbreak of rheumatism. The distribution and occurrence of rheumatic fever appeared to present no greater problem than the one with which we were already familiar with in the case of pneumonia.

Types of Rheumatism in Children.—Dr. R. H. McConnell presented this paper. He said it was interesting to note how closely the types of rheumatism in children were allied to each other. During the past three years there were about 10,000 new cases admitted to the Vanderbilt Clinic and of this number about 8 per cent. were afflicted with some type of rheumatism. He said it was surprising how often one found a heart murmur with a history of growing pains or tonsillitis. The most frequent form, tonsillitis, occurred in about 35 per cent. of the cases. In 11 per cent. of the tonsillitis cases there were complications by one or more of the other types. Endocarditis was the commonest complication. Endocarditis which was second in frequency, occurred in about 23½ per cent. of the cases, and was so closely allied with the other forms that it was difficult to separate it. He had only taken those cases with a history of shortness of breath, pain, etc. The articular forms he ranked third, although they were about as frequent as endocarditis, occurring in about 23½ per cent. of the cases. This variety had the greatest number of complications, occurring in about 60 per cent. of the cases. Fourth in order was chorea, occurring in 14½ per cent. of the cases. Fifth in the series he placed muscular rheumatism or growing pains. This occurred in 2 per cent. of the cases. Torticollis, the sixth in order, occurred in 1 per cent. of

the cases and was complicated by tonsillitis or some joint lesion. Purpura occurred in ½ per cent. of the cases. Subcutaneous tendinous nodules were seen in three cases, as a complication to some other rheumatic condition. Pericarditis occurred in about ½ per cent. of the cardiac cases, but was always associated with endocarditis. The manifestations of rheumatism in children were so many that one had to be continually on the watch for them.

Diagnosis of Rheumatism in Children.—Dr. C. G. Kerley considered this subject. He said that the age of the patient was a factor of little importance. In children under fifteen months the disease was of the rarest occurrence. The majority of cases occurred in children between the fifth and tenth years of life. Points which might throw light on a case were a family history of rheumatism, a personal history of previous attacks of rheumatism, a history of frequent angina, of frequent so-called colds, a history of chorea, of frequent attacks of asthmatic bronchitis, of recurrent attacks of protracted vomiting, the evidence of former cardiac involvement. Many cases were overlooked because of a too narrow conception of the disease. Scurvy was frequently confused with rheumatism. This was a disease of infancy rarely seen after this age. An attack of rheumatism at this early age was a curiosity. In scurvy there was no elevation of temperature, while there was a tendency to involvement of the gums. Uncooked milk and orange juice would soon establish the diagnosis. During the early months of life, joint involvement with pain and local heat and redness with constitutional disturbance almost invariably meant acute epiphysitis or arthritis due to gonococcus or other infection. Muscular rheumatism in older children might have to be differentiated from muscular fatigue caused by excessive exercise. In muscular rheumatism the pain was more pronounced at about the same time each day, and worse when the weather was cold and damp. It had been his observation in a great many instances that the first diagnosis of flat foot, of spine and of joint disease, and of bone disease in general, was usually that of rheumatism. This was largely due to lack of thoroughness in examination, and not to the absence of sufficient differential signs. Joint involvement of a rheumatic character in older children showed temperature and localized signs characteristic in themselves, differing widely from those produced by other diseased states. Endocarditis occurred in the majority of cases of acute articular rheumatism. This was one of the manifestations of the disease, and not a complication. In an obscure case it might be of decided diagnostic value, and it might be the only actual evidence of rheumatism present at that time in the patient.

The Prophylaxis and Management of Rheumatism in Children.—Dr. F. M. Crandall read this paper. He said we did not do our duty by the rheumatic child if we treated only various symptoms as they arose without instituting prophylactic management. Even if we accepted the infectious theory of rheumatism, we should still continue to consider certain conditions as predisposing causes, the prevention of which must be an important part of prophylaxis. He considered the prevention of rheumatism under six headings: Clothing, exercise, hygiene, climate, diet, and prophylactic medication. The rheumatic child should wear flannels at all times, though thin ones in summer. Tepid and cool baths should be given even more regularly than to a normal child. He objected to the custom of exposing the legs of children to the cold. He recommended proper care of the throat, the removal of adenoids and large tonsils, as the throat was one of the most frequent portals of entry of the rheumatic infection. Exercise and outdoor life should receive particular attention. There were days of damp east winds when children of rheumatic tendency should not go out on the streets. However, they should not be deprived of proper and sufficient exercise. The parents of these children should be impressed with the importance of sending for the physician at every attack of joint pains, tonsillitis, influenza, etc. The mildest attacks were worthy of attention. The average child did well at the seashore during the summer, but in his experience not so well in the mountains at too high an altitude. Damp valleys or lake regions where there were many fogs were not to be advised. The rheumatic child more often required tonic treatment than did the average child. They were prone to be anemic, and should receive iron freely. Codliver oil was also valuable. Maintaining the nutrition by judicial feeding and exercise and the administration of codliver oil and iron were important features in prevention. He was convinced that we could do much by the use of salicylic compounds to prevent acute outbreaks of rheumatism. He could not urge the necessity too strongly of administering salicylate of soda in the intervals between attacks. Whenever there was a recurrence of rheumatic symptoms he advised the use of salicylate of sodium in doses of from three to five grains, three times daily, for one of two weeks of each month, for months at a time.

Dietetic Treatment of Rheumatism in Children.—Dr. W. Gilman Thompson read this paper: He said that the dietetic treatment of rheumatism had been particularly disappointing, as was often the case with climatic and other hygienic influences. If it were admitted that rheumatism was an infection, there was no reason for believing that it could be influenced specifically by any preventive diet. Rheumatism which produced rapid anemia and digestive disturbances might be aggravated by overfeeding, or a convalescence prolonged by underfeeding. The dietetic treatment of this disease was completely covered by the fundamental principles of feeding any child, namely, to select foods for their digestibility and to meet the demands of growth and development. During an acute attack the diet did not differ from that of an adult, which should consist of milk and bread or crackers and milk. For some time with milk the diet should continue to be chiefly farinaceous, but not saccharine. A little later it might be varied with broths, soups, chicken tea, custards, plain gelatin foods, etc. It was safest to allow no red meats for at least ten days or a fortnight after the subsidence of all fever and other acute symptoms. In cases of retarded convalescence there was less risk of inducing relapse by an increase in proteids, etc., than in prolonging the impaired nutrition and failing to increase the resisting power of the body. He thought that it was undesirable to withhold meats and sugars continuously with the idea of preventing a recurrence of the disease, although these articles of diet should be restricted within moderate limitations. The growth and development was more urgent than the alleged specific influence of any one variety of food. Even in cases complicated by chronic nephritis he had seen a decided improvement follow a reasonable addition to proteid food to the dietary. He encouraged the drinking of a copious amount of water at all times, but especially during acute attacks. The addition of fruit flavors would aid in the attainment of this object. In rheumatism there was no food or single class of foods which was curative, and there was none which was causative of the disease.

Medicinal Treatment of Rheumatism in Children.—Dr. William Shannon read this paper. He said that clinical experience had taught that lack of suitable diet was a potent factor in the production of rheumatism in children, and, consequently, it was difficult to discuss the medicinal treatment apart from the dietetic. It was well to administer a dose of calomel at once, one-sixth of a grain every half hour, and follow with a saline cathartic. This not only cleaned out the digestive tract, but acted as a cholagogue and diuretic and also obviated the cerebral effects of salicylic acid. This was at present regarded as the best remedy for all types of rheumatism. However, they exerted no permanent influence on the diathesis which was the cause of the disease. Natural salicylic acid was preferable to the artificial drug. Salicylate of sodium was the preparation which in his experience had given the most satisfactory results. It should be given in as palatable form as possible. It should be given on an empty stomach, though

in some cases it was better borne after meals. A child from five to ten years might be given from five to ten grains every third hour until there was a marked amelioration of the symptoms, which usually occurred in from twelve to thirty-six hours. After this the same dose was continued for four or five days. He had added to the above treatment powdered rhubarb, two or three grains, sodium bicarbonate, ten to twenty grains, three times a day, before meals, and had found that the mixture gave better results than the salicylate alone. After the salicylate was stopped the rhubarb and soda mixture was continued for several weeks. If endocarditis accompanied the other symptoms, its presence did not contraindicate sodium salicylate. If the patient was restless and could not sleep, three or four grains of Dover's powder, or a hypodermic of morphine, would slow the heart's action and secure sleep. No drug could protect the heart as well as complete physical rest. Pericarditis and pleurisy required the same treatment. After the acute stage was passed, iron and iodides were given with a view to the absorption of the exudates. Syrup of the iodide of iron in large doses gave good results. Success in the treatment of chorea depended upon our conception of its etiology. If we regarded it as rheumatism and treated it as such, results were satisfactory. Salicylates were the best remdies for rheumatic tonsillitis. Acetanilid combined with caffeine citrate gave relief from the aches and pains which accompanied this symptom. Purpura rheumatica was benefited by iron and arsenic after the use of salicylate. Tincture of opium and tincture of aconite applied to the joints gave relief.

Dr. L. Emmett Holt said that rheumatism was very infrequent during infancy and very often it was diagnosed when it did not exist, and again it was often overlooked in older children. He had seen cases of multiple arthritis of gonorrheal origin pronounced to be unquestionably rheumatic for several weeks before its true nature was learned. The youngest person attacked by rheumatism that he ever saw was a child aged 15 months. He believed the comparative immunity of children from rheumatism was due to something that pertained to the diet, or the child's surroundings. There was no specific diet for rheumatic children, and no article of diet could cause rheumatism. He believed one of the reasons why children had rheumatism so infrequently was probably because of their liquid diet. Two years ago, while in London, he said he was struck by the large doses of salicylates that were given rheumatic children, half an ounce being given in twenty-four hours in bad cases. He approved of the plan of giving twice as much bicarbonate of sodium as of salicylic acid; when it was given in this way children could tolerate larger doses.

Dr. Henry Koplik said that although we were coming to look at rheumatism, acute or chronic, in children as an infectious trouble, there was no question but that the infection was different in different cases. Rheumatism manifested itself in many ways, sometimes as chorea, sometimes as erythema nodosum, sometimes as purpura hemorrhagica, etc., and this showed the confusion which existed regarding the true nature of the disease. There was no dietetic treatment for rheumatism, but we should always bear in mind the importance of preserving the patient's nutrition. Rheumatism was rare n young infants not because of the liquid diet so much as because certain things were not developed in them which were developed later in life; they had no tonsils, and were not subjected to the dangers of adenoids, or adenoid operations; therefore it was much less common prior to the second year of life. If the disease had not too far invaded the organism, the heart being intact and the child comfortable, he believed much could be done in the way of prophylaxis. But if the disease got beyond certain lines it was one of the most severe affections of childhood. No physician could make a good child out of a bad rheumatic subject, and in most cases his best efforts would be balked. The remedies recommended in the treatment of rheumatism were legion.

Dr. J. E. Winters said that the specific which uniformly and unfailingly neutralized and counteracted the rheumatic virus was a product of the soil. Wintergreen oil was 96 per cent. methyl salicylate, and 169 grains of methyl salicylate would yield 138 grains of salicylic acid, the latter being converted in the intestine into salicylates.

Dr. Henry L. Coit of Newark said he had never seen a case of rheumatism in a child under one year of age but once, and then it was associated with endocarditis. One full dose of calomel was more effective in the initial stage than fractional doses of calomel. He relied more upon salicylate of quinine, because of its supporting action upon the heart, and its use was pushed even in the febrile stage of the disease. He had also obtained good results from the use of nascent iodine, especially in the relief of pain. Fruits and milk he employed during convalescence, but never at the same time.

Dr. Louis C. Ager of Brooklyn said that the salicylates were used principally as analgesics. The anemia which resulted was as much from the action of the salicylates as from the action of the rheumatic poison.

Dr. J. Finley Bell of Englewood said he had never seen cyanosis follow the use of the true salts, but only when the synthetic forms were employed.

Dr. James J. Walsh said that all were agreed that rheumatism appeared like an acute infectious disease, but he did not believe that it was due to any one microorganism. There were mild pyemias which presented many manifestations and had to be treated in various ways, according to the manifestations, and he was of the opinion that rheumatism belonged to one of these forms.

Dr. Henry Dwight Chapin said that when a child had "growing pains" one should keep in mind the muscular wearinesses which occurred in growing children, as well as certain bruisings which were so common. If the child limped it should be carefully examined for bruises. In rheumatism pains occurred in the morning as well as afternoon; but if the pains resulted from incomplete tissue metamorphosis they appeared after play. Dr. Chapin was of the opinion that if the salicylates did not relieve the rheumatism in a short time they would fail to relieve in that particular attack.

Dr. Henry Heiman said that practically all were agreed that rheumatism was an infectious disease. He called attention to the blood count as a possible means of conferring this immunity in children. In the new born the white cells numbered from 19,000 to 20,000, while in adults they numbered from 7,000 to 11,000. Whatever salicylic acid preparation was used should come from a reliable source. He thought it was better to write for salicylic acid and bicarbonate of sodium together; this would form a pseudospecific. The intermittent treatment should be employed as in syphilis and malaria.

Dr. W. Gilman Thompson said he did not believe there was any specific food for the cure of rheumatism, nor could any food be used as a prophylactic.

College of Physicians of Philadelphia; Section on General Medicine.

At a stated meeting held December 11 Dr. F. J. Kalteyer demonstrated "A Case Presenting Unusual Features of Angina Pectoris." The patient was a young woman, 27 years old, who had scarlet fever and other diseases of childhood and later an attack of rheumatic fever. Following the last disease she had observed palpitation of the heart and breathlessness on exertion, and in a short while she began to suffer from attacks of precordial pain of varying grades of severity. Relief was obtained from the use of nitroglycerin in the form of spirit of glonoin, which at the time of report the patient was taking in amounts up to 50 minims daily. The heart was greatly enlarged, especially toward the left, a thrill was palpable in the precordium and diastolic and systolic murmurs were audible at the aortic area and a presystolic murmur in the mitral

area. Dr. Wm. E. Hughes presented a communication entitled "The Clinical Significance of Precordial Pain." He omitted from consideration pain due to myalgia and neuralgia, but dealt especially with that referable to functional and organic disease of the heart and the aorta. Such pain is not uncommonly observed in connection with intoxication with alcohol or with lead, with anemia and chlorosis, with myocardial disease, and dilatation of the heart and valvular disease and inflammation of the aorta and with angina pectoris. Dr. D. L. Edsall presented a communication entitled "Clinical and Experimental Observations on the Effects of *X*-rays in Certain Medical Diseases." He referred to the fact that in certain cases of leukemia good results are obtained from the use of the *x*-rays, while in certain others the reverse is the case. In the former it has been found that the metabolic activity is increased, while in the latter it is not. The view was proposed that under the conditions first named the rays are capable of inducing a condition of autolysis affecting more especially the leucocytes. Attention was called also to the disastrous effects observed in some cases of pernicious anemia from the therapeutic employment of the *x*-rays, the result being attributed to a primary depression of the metabolism, which under favorable circumstances may be followed by a secondary increase. Dr. J. Allison Scott read a paper entitled "A Clinical Report of Cases of Typhoid Fever Complicated by Suppuration, with Special Reference to the Changes in the Number of Leucocytes in the Blood." He explained that the leukemia of the disease must be due to some influence affecting adversely the multiplication of leucocytes, as even in cases in which suppurative and other conditions occurred that ordinarily gave rise to leucocytosis, this does not occur or if it does occur the degree of leucocytosis is much lower than is usually the case. He cited cases presenting various forms of suppuration and other complications, such as ovarian abscess, suppurative parotitis, pneumonia, perforation of the bowel, bone abscess, etc., in which this doctrine seemed to be exemplified. Dr. J. M. Swan presented a communication entitled "Report of a Case of Paratyphoid Fever." The patient presented the classical symptoms of typhoid fever with the exception of the agglutination reaction. Blood-cultures proved negative, but bacilli resembling the paratyphoid bacillus were isolated from the urine and these were agglutinated by the patient's blood-serum, but not by serum from cases of typhoid fever.

Philadelphia Pediatric Society.

At a stated meeting held January 9, Dr. S. McC. Hamill presented "A Case of Internal Hydrocephalus." The patient was a girl about fourteen years old who had an enormous head with remarkably little distortion of the face and with a considerable degree of intelligence. Dr. Hubley Owen demonstrated "A Case of Acute Bronchopneumonia Complicated by Symptoms of Multiple Neuritis." The patient was a child about seven years old who, following an attack of bronchopneumonia, presented weakness in all four extremities, with slight wrist-drop and foot-drop, steppage gait, degenerative electric reactions, abolition of knee-jerks, tenderness in the course of the nerves, and control of sphincters. Dr. Owen also demonstrated "A Case of Spastic Paralysis Following Scarlet Fever." The patient was a child about three years old, who in the sequence of an attack of scarlet fever exhibited weakness of the lower extremities, with increased knee-jerks and ankle-clonus on side, and also retraction of the head toward the right and deflection of the face toward the left. There was no evidence of Pott's disease and intelligence was unimpaired. Dr. Eleanor C. Jones exhibited "Specimens of Congenital Adenosarcomata of the Infant Kidney, with Report of a Bilateral Case." The specimens came from a child seven months old with swellings in each loin, which after death were found to be due to a large adenosarcoma involving each kidney, the organ being distorted and expanded over the surface of the new growth. Dr. Samuel McC. Hamill presented a communication entitled "A Case of Infection by the *Micracoccus Hæmorrhagicus*." The following officers were elected for the ensuing year: *President*, Dr. Alfred Hand, Jr.; *Secretary*, Dr. Maurice Ostheimer; *Treasurer*, Dr. Howard Childs Carpenter; *Recorder*, Dr. Chas. H. Weber.

Books Received.

While the Medical Record *is pleased to receive all new publications which may be sent to it, and an acknowledgment will be promptly made of their receipt under this heading, it must be with the distinct understanding that its necessities are such that it cannot be considered under obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

Etudes sur le Traitement des Fractures des Membres. By Doctors J. Guilloux, L. Eissenbeck, J. Faidherbe, A. David L. Merveille and Ad. Platel-Desclée. De Brouwer et Cie., Lille, France.

Die Blinddarmentzündung (Perityphlitis) In der Armee Von 1880-1900. By Dr. Stricker. 23d Edition. 8vo, 110 pages, illustrated, muslin. August Hirschwald, Berlin. Price 4 Mark.

The Signs of Internal Disease with a Brief Consideration of the Principal Symptoms Thereof. By Pearce Kintzing, B.Sc., M.D. 4to, 374 pages, illustrated, English silk. The Cleveland Press, Chicago. Price $3.00; half morocco, Edited by J. Rousset, 8vo, 1,644 pages, illustrated, paper. $4.00.

Bodily Deformities. By E. J. Chance, F.R.C.S. Eng. Edited by John Poland, F.R.C.S. Eng. Second Edition, Vol. One. 12mo, 315 pages, illustrated, muslin. Smith, Elder & Co., London. Price 6/.

The Physiology and Therapeutics of the Harrogate Waters, Baths and Climate Applied to the Treatment of Chronic Disease. By William Bain, M.D., M.R.C.P., and Wilfred Edgecombe, M.D., F.R.C.S. 8vo, 300 pages, muslin. Longmans, Green & Co., New York. Price $2.60 net.

The Changes Produced by Inflammation in the Conjunctiva. By M. S. Mayou, F.R.C.S. 8vo, 179 pages, illustrated, muslin. William Wood & Company, New York. Price $2.75 net.

Lectures on Tropical Diseasees. By Sir Patrick Manson, K.C.M.G., M.D., LL.D., F.R.C.P. 8vo, 230 pages, illustrated, muslin. W. T. Keener & Co., Chicago. Price, $2.50 net.

Handbook for Attendants on the Insane. By the Medico-Psychological Association. Fourth edition, reprinted with revised regulations. 12mo, 158 pages, illustrated, muslin. W. T. Keener & Co., Chicago. Price, 80 cents net.

L'Anesthesie Chirurgicale par La Stovaine. Par le Dr. Leon Kendirdjy. 12mo, 203 pages, paper. Masson et Cie., Editeurs, Paris, France.

A Pocket Formulary. By E. Quin Thornton, M.D. Seventh Edition. 32mo, 287 pages, leather. Lea Brothers & Co., New York. Price, $1.50 net.

L'Injection Tracheale Simplifée. Par le Dr. Henri Mendel. 12mo, 79 pages, illustrated, paper. F. R. de Rudeval, Paris, France. Price, 1 fr. 50.

The Diseases of Infancy and Childhood. By Henry Koplik, M.D. Second Edition. 8vo, 885 pages, illustrated, muslin. Lea Brothers & Co., New York. Price, cloth, $5; leather, $6, net.

The Surgical Treatment of Chronic Suppuration of the Middle Ear and Mastoid. By Dr. Seymour Oppenheimer. 8vo, 425 pages, illustrated, cloth. P. Blakiston's Son & Co., Philadelphia.

Squibb's Materia Medica. 1006 Edition, Part II. 8vo, 304 pages, illustrated, muslin. E. R. Squibb & Sons, New York.

Physiologie und Pathologie des Mineralstoffwechsels. Von Dr. Albert Albu und Dr. Carl Neuberg. 8vo, 255 pages, muslin. Julius Springer, Berlin. Price, 7 marks.

Materia Medica, Pharmacy, and Therapeutics. By Samuel O. L. Potter, A.M., M.D., M.R.C.P. Tenth Edition. 8vo, 914 pages, muslin. P. Blakiston's Son & Co., Philadelphia.

A Handbook of Climatic Treatment, Including Balneology. By William R. Huggard, M.A., M.D., F.R.C.P. Lond. 8vo, 536 pages, muslin. Macmillan & Co., Ltd., New York. Price, $4.00.

Totals	2,591	299

The Cure of Leprosy.—Isadore Dyer believes that leprosy is curable. He speaks of the two forms of the disease, that of nerve type and that of skin leprosy. These two forms start alike but they vary as the symptoms develop. The writer declares that the treatment of leprosy must be based on the individual case. The results of his work with various remedies in Louisiana have been based on the physiological state of the patient. He has met with no case of leprosy in early or not advanced types that has failed to respond to treatment. In those cases in which treatment has been instituted early enough a certain number have recovered. In ten cases which he describes the possibility of cure is demonstrated. Out of the remedies which he has employed the only ones giving results are; strychnine antivenomous serum, chaulmoogra oil, and chlorate of potassium. The writer has experimented considerably with chaulmoogra oil and he has found that this oil when in as crude a state as possible and still remaining liquid, given in maximum doses, more nearly approximates a specific for leprosy than any other treatment so far suggested. The writer then emphasizes certain points which have impressed him in the treatment of these patients: Full diet, restricting only indigestible foods, is indicated. The disease seems in no wise to be affected by fish or any other particular article of diet. Baths are essential in the treatment. Hot baths, twice a day, with or without soda, are effective. The patient needs tonics, and febrifuges, and should be watched for intercurrent or complicating diseases, such as malarial infection, pleurisy, pneumonia, grippe, and the like. Strychnine is a *sine qua non* in the treatment of leprosy. The sort and size of dose may be regulated by the patient himself. Chaulmoogra oil is better endured before meals than after. The easiest way to take it is in capsules, in hot milk, or in milk of magnesia. The dosage should first be small—three drops—and increased every second or third day up to one hundred and twenty or one hundred and fifty drops at a dose. The oil may be given in pill form,—combined with extract of nux vomica, or with tragacanth and common soap. Persistence in treatment is necessary, and the patient must be individualized. When all evidences of the disease have disappeared the physician should insist upon continuance of treatment. Although this may not be *Journal of Medicine.*

Cancer of the Uterus.—E. de Arcangelis believes that cancer of the uterus is surgically curable, but the intervention must be early enough to enable the surgeon to destroy it before certain barriers have been passed by the disease, and while it is a purely local process and not a generalized disease. The diagnosis must be an early one, as when marked symptoms have shown themselves it is too late to hope for cure. One great difficulty in getting an early diagnosis is the habit among women of applying to a midwife, instead of a physician, for advice in any uterine trouble. Another is that the early symptoms of uterine cancer are so slight that they do not alarm the patient and cause her to seek advice. The people should be educated up to a knowledge of the fatal nature of the disease and its insidious approach, and to the value of early operation. Age near the climacteric and low social position are factors that cause suspicion of the disease. Any irregular loss of blood on slight occasions, as from coitus, or the use of a douche, should cause an examination; so should every leucorrheic discharge at the climacteric. Bimanual examination and the use of the speculum aid materially in the diagnosis, and the excision of a bit of any nodule, or the examination of scrapings from the inside of the uterus, is of the utmost importance.—*Archivio di Ostetricia e Ginecologia,* November, 1905.

Health Reports.—The following cases of smallpox, yellow fever, cholera, and plague, have been reported to the Surgeon General, Public Health and Marine Hospital Service, during the week ended February 10, 1906.

SOME PROBLEMS IN THE TREATMENT OF PNEUMONIA.*

By EGBERT LE FEVRE, M.D.,

NEW YORK.

In considering the problems involved in the treatment of acute croupous pneumonia, the physician's individual conception of the nature of the disease, the cause of the different clinical phenomena, and how these causal factors are to be themselves controlled, or their effects on the different structures of the body to be antidoted or mitigated, will dominate his treatment. If he has a well-defined belief and the courage of his convictions, his plan of treatment will be more or less definite. If he has no definite idea of what is to be accomplished by his treatment, he will try any and every plan proposed; he is always striving to find in the text-books or monographs some hard-and-fast scheme, and he readily accepts the one which is presented most dogmatically, only to discard it when a more positive writer presents a new one. There is at the present time no orthodox plan for treating pneumonia. We have never known as much as we do at the present time of the cause of the disease, its pathological course, its diagnosis, the danger signals—yet we bemoan the fact that, as in days gone by, its mortality is the opprobrium of scientific and clinical medicine, although pharmacology and bacteriology have given us so many weapons to combat the other acute diseases. Pneumonia will always claim a certain percentage of victims; some will get well without treatment, or in spite of treatment used; but there is a considerable number in which recovery will depend upon the treatment.

In judging of the value of any plan of treatment, it must be remembered that pneumonia varies according to severity and type in different years, at different times of the year, and in different localities; that those who are affected are individuals differing widely in mode of living, constitution, and natural powers of resistance; that a plan of treatment suitable in one epidemic, or one locality, or for one class of people, is not always applicable, but must be modified to meet the individual case. The physician must decide on the plan of treatment, what remedies are to be used, and for how long. It all depends upon his medical judgment. The surgeon can lay down the principles and give all the details of a surgical operation, but in the treatment of such a complex disease as pneumonia this is impossible. There is so much difference of opinion on essential points, so much confusion as to the means to be employed, and such conflicting statements as to the value of certain special plans, that a paper on treatment is a discouraging task.

I feel almost like apologizing for introducing the subject again, especially as I have no antidote, or sure cure, to present. I can merely give you my viewpoint of some of the problems involved in the treatment. As long as pneumonia was considered merely an inflammation of the lungs, the principles governing its treatment were comparatively simple. They were those that were applicable to all inflammatory conditions. The fever was the index of the severity of the disease and one of its chief dangers, and every effort was made to control it. It is needless to recount the means used. Many of them still persist in the treatment to this day, and, although the original reason for their use was long ago shown to be erroneous, still clinical experience deems them to be of value. As long as attention was centered on the pathological changes occurring in the lung in the course of pneumonia, the restriction of respiratory surface and the mechanical obstruction to the pulmonary circulation caused by the consolidated lung were considered the chief determining factors in causing respiratory and cardiac failure, and active treatment, both external and internal, was used to arrest or limit the morbid process, to check the congestions and incipient exudates, to diminish the coagulability of the blood, and, when consolidation had taken place, to hasten the absorption of the fibrinous exudate, and so overcome the obstruction. Although at the present time we know that the changes in the lung are but incidents of the disease, and that the mechanical obstruction caused by the consolidated lung is only a contributing factor in the production of respiratory and cardiac failure, certain measures that were found beneficial when pneumonia was considered a local disease still remain suitable treatment for the serious complications that occur during the cause of the disease, and it is necessary that we study anew their mode of action and how they do good. At the present time pneumonia is considered an acute infectious disease, with a localized inflammation of the lung of a characteristic nature, due to the presence of the pneumococcus. The most difficult problem in each individual case is the determination to what extent the clinical phenomena of the disease are dependent on the toxemia on the one hand, and the pathological condition of the lung on the other.

How, in the light of our present knowledge, can we explain the sequence of events in mild, severe, and fatal cases? In mild cases the sudden onset, the rapidly rising temperature, and, before any recognizable change in the lung occurs, the increased respiratory rate, the greater depth of respiration, the bringing into use the accessory muscles of respiration, the dilation of the nostrils with inspiration, the almost diagnostic expiratory grunt, are pathognomonic. The circulatory phenomena are almost as marked. The cardiac action is forcible; the first sound booming; the pulse full and bounding; the systolic blood pressure high; the diastolic also increased. The patient is restless, even when there is no pain. There is sleeplessness, delirium, and in children convulsions. In mild cases and in strong, robust individuals these "sthenic" symptoms may increase in degree throughout the entire attack, until they suddenly cease with crisis.

*Read before the Medical Society of the County of New York January 22, 1905.

In severe cases the "sthenic" symptoms continue for a few days only. On the third, fourth, or fifth day according to the type, the respirations become more rapid, but shallower, cyanosis is present, and there develop gradually or suddenly all the symptoms of respiratory insufficiency. Cardiac action becomes more rapid, but less forcible, the pulmonic second sound is accentuated, the pulse loses its bounding character, the tension falls, and the pulse later becomes dicrotic and irregular. The systolic blood pressure falls, but earlier and more marked is the decrease in diastolic pressure. The entire venous system shows engorgement, and there are signs of overfilling of the right heart. The patient is apathetic, the face cyanotic, and the entire body covered with a cold, clammy perspiration. When this stage is reached, if crisis occurs, the temperature falls, symptoms of impending respiratory and cardiovascular failure disappear, cyanosis clears up, and the danger is passed.

In other cases, before the time of crisis comes, the patient dies of pulmonary edema, respiratory insufficiency, exhaustion of the respiratory muscles, or cardiac failure, and at autopsy the cavities of the right heart are found dilated and filled with clots, which may be partly decolorized and extending into the pulmonary arteries. The left ventricle is often found firmly contracted and empty, less frequently dilated and filled with recent clot.

How far are the dangerous symptoms due to curtailment of respiratory surface and mechanical obstruction to the circulation? In severe cases with recovery the symptoms of respiratory insufficiency and impending circulatory failure rapidly disappear with the crisis, although there is no change in the extent of lung involved, the degree of consolidation, or obstruction to the pulmonary circulation. In other diseases of the lung and pleura that diminish to a greater degree the respiratory surface or produce more marked obstruction to the pulmonary circulation, when the patient is quiet there is not present the rapid labored respiration or the effect on the pulmonary circulation and right heart, even though there be high temperature. The local lesion in the lung is therefore not the essential cause of the symptoms, although it contributes to the seriousness of the case and adds its own peculiar danger.

The toxemia of the pneumococcus infection must be considered the chief factor in causing the symptoms of the disease. Theoretically, this is conceded by nearly everybody, but, therapeutically, it is ignored in practice. Professor Jurgensen says: "If pneumonia is an infectious disease, it must be treated according to the same fundamental principles which experience has proven valuable in other infections." As a therapeutic maxim, the statement of Professor Jurgensen is comprehensive, but to treat the disease intelligently, it is necessary that we know what is the nature of the action of the toxemia on the different organs of the body. Is it a stimulant, an irritant, or a depressant? Does it act on one organ or system of organs in one manner and on others in an opposite? Are its early and late effects of a different nature, or are the late effects the result of the early ones? Upon our opinion will depend the general management and the choice of remedies to control the various symptoms and complications that arise at different periods of the disease.

I believe the primary and essential action of the toxemia of the pneumococcus infection is that of stimulation. Its effect upon the general nervous system is shown by the restlessness and sleeplessness, and in children by convulsions. The respiratory symptoms that occur with the onset of the disease, the rapid, deep breathing, the using of the accessory muscles in both inspiration and expiration, the fuller expansion of the thorax, the intensified respiratory murmur over the unaffected portion of the lung, indicate that the entire respiratory mechanism is being stimulated. The respiratory phenomena cannot be due to fever alone, for they do not correspond to the degree of temperature, and in other febrile diseases they are absent, or present in a much less degree. They cannot be attributed to the pain alone, because they occur even when pain is absent; nor dependent upon restriction of respiratory space, for they occur before there is much restriction and disappear with the crisis, although the same amount of pulmonary involvement exists as when the respirations were so much disturbed. The fever, pain and pulmonary consolidation only add their quota to the respiratory symptoms, although later they may be determining or contributing factors in producing respiratory failures. The cardiovascular system shows like signs of stimulation. The rapid and overforcible action of the heart, the full, bounding pulse, the high systolic blood pressure, all show that the functional activity of the heart is increased.

The above respiratory and circulatory phenomena present during the early period of the disease may continue throughout, increasing in intensity as far as the symptoms of stimulation are concerned, and never showing any signs of respiratory or circulatory failure; but in most cases, sooner or later, according to the severity of the disease, the age, habits, previous physical condition or constitution of the patient, there appear gradually or suddenly the signs of either general weakness or insufficiency of some organs, or system of organs, most frequently respiratory, or circulatory, or both. The respirations become more rapid, but shallower. They lose their full, deep character, the respiratory muscles contract spasmodically but with less effect, the amount of tidal air is markedly reduced, there is imperfect ventilation of the alveoli of the unaffected portion of the lung, and cyanosis develops. The cardiovascular changes are, increased rapidity of the heart (120 or more), the pulse becomes short, dicrotic, and of low tension; there is evidence of imperfect filling of the arteries and accumulation of the blood on the venous side, with overfilling of the right heart, and engorgement of the pulmonary circulation. To what are we to ascribe these changes? Is the nature of the action of the toxemia changed? Is there now a depressant or paralyzing action on certain structures, which action was masked by early stimulation and the effect of fever, pain, and pulmonary involvement? We know that in infectious diseases, according to the degree of the toxemia and length of time it has been active, there are parenchymatous changes in all organs, and especially in the heart muscle. In fatal cases of pneumonia this is often present. Yet in a considerable percentage of cases it is not sufficient to account for the degree of cardiac insufficiency noted during the latter period of the disease.

I believe the stimulation of the early period of the disease is accountable for the later failure—that it is a true exhaustion that follows the excessive work that the respiratory and circulatory system has had to do. We have its analogy in the exhaustion that follows toxic drug stimulation in the pharmacological laboratory. I never see a case of pneumonia but I wonder whether he can stand the pace, for he is in an endurance race against time, the time of the crisis. If the pace has been rapid from the start; if he is handicapped by age; if his resisting powers have been impaired by work, worry, bad surroundings, or improper or insufficient food; if his

nervous system has been rendered unstable by alcoholic or other excesses; if he is suffering from structural disease, the chances are against him. Proper treatment alone is able to aid him, and it will do the most good the earlier in the disease it is given.

If the pneumotoxin has the action I have described, then there are definite indications for treatment at every stage of the disease. From the very onset our efforts should be directed to controlling the toxemia and its effects: (1) By limiting the production of the toxin in the lung and elsewhere; (2) by antidoting it after its absorption into the blood; (3) by diminishing its amount through free elimination, and (4) by neutralizing or combating its effect on the organism.

As the pneumotoxin is chiefly produced in the affected area of the lung, numerous treatments have been proposed to limit the extent of the pulmonary involvement. To control the pulmonary congestion abstraction of blood by venesection, leeching or wet cups, withdrawal of blood from the lung to the surface of the body by dilatation of the superficial blood vessels through counterirritation, hot applications, etc., or the action on the inflamed area, by the ice bag, cold coil, or cold pack, have been advised. Each method has its advocates, who believe that their plan is efficient, or even curative. All these means have a use, and, in proper cases, do give relief to the patient. They often seem to influence the circulation of the unaffected portion of the lung, and possibly in this manner prevent more widespread involvement; but beyond this effect I have never been able to see that they affected the inflamed area itself, or hastened its resolution.

To act directly on the pneumococcus in the lung, either by destroying it, diminishing its vitality, or rendering it less virulent, or by antidoting the pneumotoxin, creosote for its compounds, both by inhalation and internally, sodium salicylate, carbolic acid, salol, quinine, and other members of the antiseptic group have been advocated. Specific action has been claimed, and histories and statistics have been published to prove their value. The advocacy of these remedies by trustworthy observers, in whose judgment we all have confidence, should cause us not to ignore their possible value. At one time or another I have given them all a thorough trial. I have never seen any specific action, but in special cases, given at the right time, I am convinced that they often exert a favorable influence upon the disease. Time and again I have seen irreparable harm done by their injudicious administration or too long continuance. If they are to be of service, or to be administered with safety, it is during the early stage of the disease. When the symptoms of cardiac and respiratory exhaustion are present their use is contraindicated. The time has then gone by when they can be given with safety. Any possible effect they can have on the pneumococcus, or the pneumotoxin, is more than counterbalanced by their depressing action on the general nervous system and other organs. Quinine is an exception to the rule. Given in moderate doses, even late in the disease, it does not produce any depressing action. But I have never seen such definite good effects from it that I consider it of use. In judging of the value of these drugs in controlling the disease, the effect on the temperature, or the fact that the disease more often terminates by lysis than by crisis must not be taken as a guide. Given in sufficient doses, they will reduce the temperature; but unless, with the fall of temperature, there is a corresponding improvement in the nervous, cardiac, and respiratory symptoms, they are not benefiting the patient. Sthenic cases bear them better than the aged, the debilitated, and the alcoholic.

With the already known fact that pneumonia was a self-limiting disease, the discovery that the pneumococcus was the infectious agent and encouraged by the success that attends the treatment of other infectious diseases, especially diphtheria and tetanus, with antitoxins we were in high hopes that an antitoxin would be produced that would be as efficient in this disease. Up to the present time no such serum has been produced. All the sera thus far introduced have not been antitoxic or antifectious enough to justify their use, although some writers claim that they have seen good effects.

As at the present time we have no proven means for preventing or controlling the production and absorption of the pneumotoxin or antidoting its action after it had been absorbed, our chief effort must be directed towards the elimination of the toxin as rapidly as possible and combating its effect on the different organs. We have no definite knowledge of the avenues by which the toxins of pneumonia are eliminated, nor the form in which they leave the body. We are therefore compelled to use the means that have been found most efficient in other acute and chronic toxemias; namely, catharsis, diaphoresis, and diuresis. All these means should be judiciously used from the very beginning. They should not exhaust the patient. The using of calomel and a saline cathartic at the first visit is the orthodox method of procedure, but after this initial dose too little attention is given to the eliminative power of the intestines. As long as the bowels act once a day, it is deemed sufficient. Unless there is some counterindication, I use saline cathartics freely during the early days of the disease. Sweating should be produced by external means if the toxemia is urgent, and the same means employed as in the treatment of acute uremia; but as the hot packs, or hot-air baths, are somewhat depressing, active diaphoresis is not indicated, unless the toxemia is very profound, and it is impossible to get sufficient action of the kidneys. Pilocarpin should not be used, as it is extremely dangerous in pneumonia. On the other hand, the free use of liquor ammoni acetatis, citrate of potassium, and hot drinks, especially hot water, are useful.

The chief reliance is on elimination by the kidneys. For this purpose water, either plain or aerated, should be given plentifully. In nearly every case of pneumonia the urine shows some albumen, indicating that there is kidney irritation—probably due to the action of the toxins—and dilution of the urine is called for. Usually the urine is decreased, high colored, and concentrated. The rapid, deep breathing and the free perspiration that are present cause a larger amount of water to be eliminated by other channels, and, unless an extra quantity of water is given, the urine decreases. On account of the presence of nausea and vomiting in some cases, and in others the tendency of the stomach to retain the fluids given, a free administration of water by mouth is prevented. Under such circumstances there should be given, three or four times a day, enemas of normal saline solution (drink enemas). Water is very rapidly absorbed from the bowels, and is followed by free diuresis. In the early period the stimulating diuretics should not be given. The alkaline mixtures, as the A. B. C. diuretic, citrate of potassium, cream of tartar lemonade (which is a very agreeable and refreshing drink), liquor ammoniæ aetatis (half ounce doses every two, three, or four hours) are the most serviceable. Drinking water as hot as can be taken is well borne by many cases in which nausea and vomiting are present.

Many cases suffer from lack of water, because of the fear that if water is given the patient will not be able to take sufficient nourishment. It is better to give the needed water, as most patients are overfed. Anyone who has personally gone through an attack of pneumonia and has had milk, broths, etc., given *ad nauseam*, when what he has craved most was a good drink of water, will appreciate the hardship. Later in the disease, when there is circulatory failure, the use of diuretics of the theobromine group may be used to meet indications.

In those cases in which the patient seems to be overstimulated by the toxemia, when the cardiac action is excessive, the pulse very full and of high tension, or where the kidneys are affected and the urine highly colored, venesection is indicated, the amount of blood withdrawn being governed by the effect. Enough should be taken to lower the tension of the pulse and quiet the heart. If there is fear of reducing the blood mass too much, normal saline may be introduced into the veins, or given by hypodermoclysis. There are two periods when venesection is indicated: early in the disease for the toxemia, and later, when its purpose is to reduce venous stasis.

It has been claimed that oxygen, when given systematically throughout the disease, has the power of diminishing the toxemia. We have already heard tonight of the value of fresh air. Formerly, through the mistaken idea that a pneumonia patient should be kept as warm as possible, all air was excluded from the room. The treatment of other infectious diseases by the fresh-air method has overcome popular prejudice. I fear, however, we are in danger of bringing a very valuable plan of treatment into disrepute by overdoing the matter in pneumonia. Fresh air is needed, but low temperature is not beneficial. I do not think the temperature of the sick room should fall below 60 degrees F. I generally try to keep it about 65 degrees F. Experience has shown that, whenever tuberculous patients who are taking the open-air treatment contract pneumonia, they do best when protected against low temperature. Cold is not an essential element of the open-air treatment.

"As we cannot cure our patient, we must endeavor to keep him alive until he cures himself." To do this it is necessary to combat the effects of toxemia on different organs of the body. The treatment will, of necessity, be symptomatic, but it is none the less rational. All agree that the powers of the patient should be conserved, and, when the powers are failing, should be assisted. But there is great difference of opinion as to how this can best be done. Believing that the grave conditions that occur in the late days of the disease—the respiratory insufficiency and cardiac failure—are, in the major part, due to the exhaustion of these systems due to the excessive functional activity caused by the stimulation of the toxemia, I consider that at the very beginning we should try to abate this overwork. Granting that the symptoms are those of stimulation, what should be our guide for the administration of medicine to control it? Does it affect chiefly the central nervous system, or does it also have some action over the neuromuscular mechanism of the heart and lungs? It is impossible to answer many of these questions definitely, or to fortify our conclusions with experimental data. I believe that the action of the pneumotoxin is a widespread one and shows, just as other poisons do, an individual variation in its effects on the nervous system and organs. Generally the ushering-in symptoms give indication as to what portion is most susceptible to the toxemia. In the majority of cases the chill, restlessness, characteristic insomnia, cardiac and respiratory symptoms show that the nervous system, and especially the medullary centers, are acted upon. There is a great difference of opinion as to whether or not we should actively combat the above symptoms. Personally, I believe that they should be controlled, using such means as are indicated in individual cases. Rest in every sense of the word is necessary in all cases. Good nursing and proper surroundings are conducive to this. To the head, cold compresses or ice bags, and over the chest cold compresses, as recommended by Dr. Baruch, have a sedative action on the nervous system, and act favorably upon the heart and respiratory muscles as well. I believe most of the good effects that have been ascribed to the ice bag in controlling pneumonia are due to the action of cold on the heart rate. There are cases in which it is necessary to use the bath treatment as fearlessly as in typhoid fever. Fortunately, these cases are rare. The indications are not so much the high temperature as the condition of the nervous system, where the toxemia seems to be overpowering it. In this condition the high temperature is a part, but not the cause of the symptoms.

When quiet, good nursing, eliminative and simple hydropathic measures fail to control the restlessness, insomnia, delirium, and other nervous symptoms; when there is pain and harassing cough, should active treatment be used? I believe that sleep and freedom from pain should be procured as early as possible, and the patient kept quiet and comfortable. When there is pain, opium or one of its alkaloids generally acts best. The form to be used will depend on the case. Morphia, hypodermically, is best suited for the initial dose. Frequently the statement is made that morphia, while relieving the pain, has made the patient more nervous and has accelerated the heart. The practice of combining atropia with morphia is, in the majority of instances, accountable for this. In most cases in which morphine is given for relief of pain, the action on the medullary centers is not desired, and so atropine is given to antagonize it. In pneumonia this antagonistic action is not wanted. The respiratory center and heart are, in pneumonia, especially susceptible to the action of atropine; it is therefore contraindicated in the early stages of the disease. There are individuals whom opium and morphine render restless and semidelirious whenever given; if this idiosyncrasy is known opium should not be used. When opium does not act well, or when pain is not present, the bromides, or chloral, either singly or in combination, or the synthetic hypnotics, may be used to induce sleep. In the early days of the disease I have never seen these drugs produce any bad effects. When rest and sleep are obtained at the beginning, much less medication is needed later to quiet the patient. With the control of the nervous symptoms there is generally improvement in the respiration; it is less rapid. If full expansion of the thorax has been prevented by pain, the breathing becomes easier, cyanosis disappears, providing the medicine has not been pushed too far. It is especially important to relieve pain, when it prevents the patient from breathing easily, except when in one position. When there is no pain, but the patient is breathing very rapidly, although there is no evidence of imperfect oxygenization, heroin is useful. In these cases the rapid respiration is apparently due to increased irritability of the respiratory center.

In the alcoholic, and certain nonalcoholic patients the restlessness and insomnia can only be controlled by the free use of alcohol. Its action in these cases seems to be chiefly sedative.

It is always a debatable question whether any car-

diac sedative should be given, when at the very onset there is a rapid overacting heart, bounding pulse, and high systolic blood pressure. The ice bag, cold coil, and cold pack give some relief, but in many of the cases do not control sufficiently. I have watched the course of cases under the care of physicians who use the old "antiphlogistic" plan of two decades ago, who at the onset of the disease give aconite, veratrum viride, and even tartar emetic, and have been surprised to see the controlling effect on the heart. Their plan is to give the sedative during the first eighteen or twenty-four hours, in sufficient doses to control the heart, and then in smaller doses at longer intervals for two, three, or four days, watching carefully the pulse, and decreasing or stopping the drug as soon as the tension falls below a certain point or there is any suspicion of dicrotism. When given in this manner, I have seen no bad effects or any late symptoms that could be ascribed to the drug. I have never had the courage to use either veratrum viride or tartar emetic. The older practitioners have gained a knowledge of the action of these drugs, which comes only with longer acquaintance. I do use aconite in those cases where the cardiac rate and power are out of proportion to the other symptoms. I rarely continue it beyond the first eighteen or twenty-four hours. The usual dose is five to ten minims (2-3 minims Old Pharmacopeia) every two or three hours. I believe aconite is much safer to use than we have lately been led to believe.

Patients with pneumonia die most frequently from cardiac failure, respiratory insufficiency, and pulmonary edema. All three are generally present in the terminal stage. In pneumonia we must be on the watch for the first symptoms of weakness, and success in treatment will largely depend on our ability to prognosticate in each case at what point the failure is likely to occur, and on our power to combat or control it at the start before exhaustion at one point throws an added burden elsewhere and causes a general failure, when all treatment is useless. Usually the first evidence is shown by the cardiovascular system. The heart becomes more rapid, the pulse small, short and dicrotic, the systolic blood pressure falls, there is imperfect filling of the arterial system and overfilling of the venous with dilatation of the right heart and engorgement of the pulmonary circulation. The remedies used to combat these symptoms will depend on our conception of the causes of the failure. That so many diametrically opposed plans have been advocated shows that there is a great difference of opinion. The primary failure may be caused by changes in the heart muscle, or by changes in the vasomotor control over the blood vessels, leading to vascular collapse. It has long been known that the toxin of pneumonia does not cause as marked weakness of the left ventricle as of the right: that, in addition to the greater parenchymatous degeneration of the right heart we have the added burden of the interference with the pulmonary circulation by the consolidated lung. This mechanical obstruction has been generally considered the exciting and chief cause of cardiac failure.

Romberg, in considering the effects on the circulation of pneumococcus infection, says: "We must consider with the heart weakness the weakness of the vasomotors; with the cardiac paralysis that of the vasomotor also." I am convinced that to the loss of vasomotor control must be ascribed the chief danger in pneumonia. I think this gives us a guide for treatment, and that it harmonizes many discordant opinions, concerning the value of certain drugs as cardiovascular stimulants. When there is loss of resistance in the arteries and arterioles producing marked disturbance of the equilibrium of the circulation, although the left ventricle is relatively strong, the pulse becomes more rapid, small, and dicrotic. The blood passes rapidly to the venous side, causing an incomplete filling of the arteries, while the veins become overfilled. The increased pressure in the veins, slight though it be, and the rapid respirations tend to cause the right auricle to be distended. The weakened right ventricle cannot empty itself against the increased pressure present in the pulmonary circulation, and there develops right-side cardiac dilatation and insufficiency with tendency to cardiac thrombosis, and later pulmonary edema and respiratory failure. To combat this condition nitroglycerin is frequently advised, under the belief that by dilating the arteries the work of the heart is decreased. But peripheral resistance is already too low on the arterial side, and nitroglycerin only makes it lower. We have no data to prove that nitroglycerin has any effect on the pulmonary circulation. Personally, I have only seen bad effects when nitroglycerin and other members of the nitrite group are given in pneumonia during the stage of vasomotor weakness. It is only indicated in pneumonia when there is high arterial tension associated with a rapid-acting heart, as occurs in cases of arteriosclerosis and nephritis. Under such conditions it should be given from the very beginning, as the rapid and forcible acting left ventricle soon exhausts itself pumping against high blood pressure. I cannot too strongly condemn the tendency of resorting to nitroglycerin whenever cardiac failure is suspected.

Against the loss of vasomotor control we have two classes of stimulants. (1) Those acting on the medullary centers—strychnine, caffeine, atropine and cocaine. (2) Those acting directly on the muscular tissue of the arterial system—digitalis, ergot and suprarenal extract. When loss of vasomotor control is associated with evidence of weakness and exhaustion of the other medullary centers, as rapid, shallow respirations and cyanosis, marked apathy of the patient, strychnine should be the stimulant selected. The dose and frequency of administration should be just sufficient to increase the irritability of the centers. If carried beyond this point, the overstimulation only hastens the time of absolute failure. I know of no drug that is able to do so much good and also so much harm in pneumonia, as strychnine, and the deceptive feature about it is that under its free use the patient's condition improves and the secondary result of overstimulation is lost sight of. Strychnine should not be a routine treatment in pneumonia. It should not be given until indications for its use are present. As I said before, a patient suffering from pneumonia is in an endurance race against the time of the crisis. The spur should not be used too early or too freely. He may need all the stimulation possible at the end. Atropine, cocaine, and caffeine are stimulants that can be used for the emergencies that occur at the crisis, although when strychnine has lost its power, we are generally leading a forlorn hope. In cases of respiratory failure both atropine and cocaine have the power to stimulate the respiratory center. I prefer cocaine to atropine, and when it is applied to the inner side of the nostrils, either as a spray or by painting with a camel's hair brush, it has a maximum effect on the respiratory center, as I have frequently seen in treating respiratory failure caused by morphine poisoning. When the vasomotor center does not respond to strychnine, or when the vasomotor loss of control occurs before the weakness of the other centers, and the giving of strychnine would unduly stimulate these centers, the blood vessels may be

acted on by digitalis, ergot, or suprarenal extract. The value of digitalis in treating vascular collapse in pneumonia is a very decided one, and there is no drug that can take its place. It is a well known clinical fact that persons whose normal blood pressure is very low do not bear pneumonia well. The cardiac rate is very rapid, the pulse dicrotic and right side cardiac dilatation occurs early. The judicious use of digitalis in these cases during the early stage, combined with aconite, slows the heart and restores the vascular tone. Later in the disease digitalis alone is indicated. When there are added symptoms of exhaustion of the other medullary centers also, strychnine may be used in combination with digitalis. Digitalis should be given in pneumonia for a definite purpose. The objection to its use has been due to the giving of large doses throughout the disease, on the theory that it has some specific action. The power of ergot to contract the arteries is conceded by all. Whether this effect is due to vasomotor stimulation alone, or to peripheral action also is undecided. The fact that the physiological action of ergot is so definitely restricted to the vasomotor center and the blood vessels causes it to be especially valuable in cases of pneumonia with low arterial tension. In alcoholic cases the long-continued use of alcohol, provided it has not induced arteriosclerosis or nephritis, has produced a depression of the vasomotor center; the capillary circulation is also abnormal. In pneumonia, in these cases, there is a peculiar lividity of the surface that is not due to cyanosis from respiratory insufficiency. The pulse has a very low tension, and the sputum is hemorrhagic and dark, not the ordinary brick dust type. Ergot, by restoring the vascular tone, meets the most urgent symptoms. In many cases of pneumonia in the alcoholic, strychnine, while improving the circulation, increases the delirium and restlessness; it is necessary to give alcohol and narcotics in order to induce quiet and sleep, but these still further disturb the peripheral circulation. The use of ergot counteracts their effects on the circulation. It should be administered hypodermically, using the aseptic preparation.

Suprarenal extract or adrenalin chloride acts on the blood vessels very rapidly and energetically, but its effects last but a short time. Its use is to be reserved for the treatment of sudden vascular collapse, where we are using every effort to keep the patient alive in the hope that the powers of resistance may finally overcome the disease. For no case of pneumonia is to be given up until absolutely dead. The diffusible stimulants—camphor, musk, aromatic spirits of ammonia, Hoffman's anodyne—are all emergency remedies.

Time does not permit me to discuss some of the other problems. The rather active treatment I have outlined, especially for the early stage, will be criticised as contrary to the present treatment—the expectant plan. If the expectant plan is merely a treatment of observation, of standing idly by until the grave conditions of the disease develop, then what I have suggested is contrary to it. If on the other hand, it means that we fully realize the dangers that are to be expected and try to ward them off, then I have only described what is to me a rational expectant treatment. The opportunity to conserve the patient's strength occurs early, and if this be the main object of our treatment, then the early stage of the disease is the stage in which the fearless and intelligent use of active measures will be conducive of the greatest good. And we should not neglect our opportunities, and wait passively until conditions arise which either contraindicate or render useless their employment. For when this stage is once passed, "all the rest is mere work of rescue, and success is a question of vitality."

52 West Fifty-sixth Street.

THE BIER TREATMENT BY HYPEREMIA.

By MAX BREUER, M.D.,

BUFFALO, N. Y.

It is Biers' merit to have unearthed the old, buried doctrines of the usefulness of hyperemia, and by applying it in a bold as well as rational and scientific manner, to have given it its proper place in surgery. Long before Bier has hyperemia been used as a remedy—in fact, all of us have used hyperemia in the form of poultices, cupping, and so on; but if we have done so, we did it unconsciously of what we were doing, mostly with the intention of drawing the blood from the inflamed area, or, in other words, with the intention of combating the hyperemia, which, according to Bier, is wrong. Bier started out from the thought that a large part of the so-called symptoms of disease (in our case, hyperemia) are not undesirable changes in the functions of the system, which changes must take place in any single case with the regularity of a natural law; in other words, that to be ill means for the organism, to live in a form, which is most adapted to the changed conditions, changed owing to some injurious factor. So has the theory of the usefulness of fever, upheld by physicians of older times than ours, come to be honored again; and a similar view in regard to inflammation was taken by Hunter, as far back as the eighteenth century, who said, speaking of inflammations, "Nature has wisely supplied the body with useful means of self-defence." Much more readily than inflammation has the fact of inherited and acquired immunity against infectious diseases been accepted, and yet that is only another form of self-defence of the organism.

Upon the basis of these deductions and from personal observations at the bedside, Bier comes to the conclusion that hyperemia is nature's own remedy, ever present where regeneration is necessary, or where the system is invaded by some enemy, be that enemy a non-living foreign body or an organized microscopic agent. While there are many ways of producing hyperemia, Bier confines himself to producing the so-called active or arterial hyperemia by hot air apparatus, and the so-called passive hyperemia or blood stasis by his rubber bandage and his cuplike apparatus. A mixed form is produced by his large suction apparatus, in which Bier has imitated, to some extent, the apparatus built by Junod, a Frenchman, published in 1834, and in which a most powerful and extensive form, a mixture of arterial and venous hyperemia, is produced.

Bier attributes to the hyperemia produced in the way mentioned a number of effects upon the system. A very striking one is the relief from pain. Everyone has witnessed the suffering of a person affected with a gonorrheal arthritis. In from one-half to one hour after the proper application of a rubber bandage above the joint, according to Bier, the pain will diminish and finally cease. Another characteristic of the artificial hyperemia is its bactericidal effect on the system. An experiment of Noetzel on the animal proves this fact: In 51 out of 67 cases, he succeeded when injecting fatal doses of anthrax spirilli and streptococci into the extremities of

rabbits, in paralyzing the effect of those microorganisms by stasis applied to the extremity. The explanation is very likely the more intimate contact of the serum with the bacteria. Another effect of hyperemia is resorption. Another is its property of dissolving blood coagula. exudates in joints and tendons, keloids, and so on. Bier compares the procedure with an irrigation system; the outflow is interfered with, and the soil inundated to an overflow. When all the canals are filled, the soil is saturated with water, and the amount of feeding water will then approximately correspond with the amount of overflowing water. The bandage in our picture is the shut-off, which causes the overflow of serum.

Now, as to the treatment proper and its mode of application. It can be stated in general that affections based on bacterial invasion are better treated by passive, the nonbacterial affections by active, hyperemia. But this discrimination is not to be considered absolutely binding. The domain of the passive hyperemia treatment is tuberculosis, especially of the joints. Hot air treatment or active hyperemia is here undoubtedly injurious. Bier was induced to try the hyperemia against tuberculosis by the observations of Farre and Travers in 1815, and Louis in 1826, observations that the coincidence of pulmonary stenosis and phthisis was a frequent occurrence. Those authors interpreted the latter affection as caused by the anemia of the lungs. The observation was confirmed by later observers, and Frerichs was able to state that tuberculosis of the lungs is the final outcome of diseases of the pulmonary artery.

The best, and for the practitioner the most advisable, form of treating tuberculous joints by hyperemia is the rubber bandage, applied rather snugly for one hour daily, the turns of the bandage covering each other halfway. While the hyperemia has to be pronounced, to be of value for such a short time, and while swelling of the limb is desired, edema must not be produced, nor a blue discoloration. Real pain or paresthesia, also the appearance of bright-red spots in the skin, as one often sees them in the twenty-hour stasis in acute septic conditions, also a cold appearance of the limb point to an excessive dosage of the procedure, and demand immediate correction. The arterial pulsation, of course, must never be stopped, or, in other words, one must always be able to feel distinctly the pulse distally to the bandage. It is unnecessary to apply the constricting bandage directly above the joint in question; on the contrary, the place for the bandage ought to be changed frequently, and to produce hyperemia in a fungus of the wrist one may apply the bandage to the upper arm. Exceptionally, Bier has used the bandage in some cases of tuberculosis during two or three hours daily—never longer.

If a cold abscess develops under the treatment, or if a patient with a cold abscess applies for treatment, the abscess is opened under local anesthesia and under aseptic conditions; but only small incisions are necessary, and a suction cup is applied. Then the wound is covered with aseptic gauze and the rubber bandage treatment is begun for an hour, as in nonsuppurative cases. Note here the difference between the Mikulicz method, according to which a cold abscess is never opened by an incision from fear of mix d infection. Such a fear is unnecessary in Biers' treatment of cold abscesses, since the suction and hyperemia produce a constant throwing out of pus and débris and finally serum, and mixed infection does not take place under proper precautions. The cups are kept in antiseptic solution, and the wound's surroundings are cleaned with some antiseptic solution and usually covered with sterilized gauze. One should refrain from all further interference, as, for instance, scraping with a sharp spoon and drainage.

Sequestra sometimes require removal. Often they are, if small, extracted by the cup; often they are absorbed, or reunited to the healthy bone tissue.

Contraindications are, of course, amyloid degeneration, advanced tuberculosis of the lungs, and large cold abscesses of joints, as they occur sometimes in the kneejoint, and faulty position of joints at the time when patients enter the course of treatment.

The hyperemia treatment, in general, dispenses with (and this is an important point) the fixation of the joint in wrist-, elbow-, and shoulder-tuberculosis. The early use of passive and active motions is necessary for good results. Knee-and foot-tuberculosis cases are made to walk in a so-called ambulatory plaster-of-Paris bandage, or in an extension apparatus.

A short review of the cases of tuberculosis treated in Bonn during sixteen months, beginning the 1st of April, 1903, may be interesting:

I. Tuberculosis of the wrist.—Seventeen cases were treated. Four of these had fistulæ and ulcerations from the beginning. In five cases cold abscesses had to be opened. Of these seventeen cases fifteen were cured, all with satisfactory mobility; three with perfect mobility. Several of these patients, when coming in showed severe anatomical destruction in the Roentgen picture, subluxation and complete stiffening of the fingers. The two remaining cases not cured were improved. One of these was a very severe case, in which cold abscesses had to be opened frequently. The average time of treatment was twelve months.

II. Tuberculosis of the elbow.—Eleven cases, five of them with fistulæ. In eight cases, abscesses were incised. Eight cases were cured; two of these were fistulous cases. Entirely normal mobility in none of the cases. In all of the cured cases satisfactory mobility. Three were improved—all fistulous cases. Average treatment nine months.

III. Tuberculosis of the foot, Chopart's joint, Lissfranc's joint, or of several joints.—Thirteen cases were treated, eight of these fistulous. In six instances incision was necessary on account of cold abscesses. Eight cases were cured; four of these were fistulous cases. Three were improved. One case was not influenced. One case later required amputation. In three cases perfect mobility was accomplished; in the other five satisfactory mobility. The average time of treatment was ten months.

IV. Tuberculosis of the shoulder.—One case was treated, with perfect result.

V. Tuberculosis of the knee.—Five cases. Two of these were beginning; one was a fistulous case. Three were cured, two of these with perfect mobility, one with slight ankylosis in good position. Two cases were improved both with pronounced ankylosis.

A number of these cases cited were discharged in such a condition that the most skillful diagnostician was not able to say which one of the joints had been afflicted. Such ideal results have

not been accomplished by the most conservative operation. By the method of extension and fixation heretofore practised in most cases of tuberculous joints we are satisfied to accomplish a recovery with ankylosis. Bier begins with passive motions soon after the treatment has been started.

In a longer series of cases, not selected, but treated as they entered the clinic and dispensary, the wrist showed a cure in 88 per cent.; the elbow in 72 per cent., and the foot in 61.5 per cent.

Upon the basis of his experience, Bier declares his method to be the best conservative means of treatment for joint tuberculosis, because it leads with the least danger, in the most simple and inexpensive way, to results, which no other method can accomplish. Poor results in other hands have been produced by faulty technique.

During the last year, Dr. Klapp, Bier's chief surgeon, has modified the treatment of joint tuberculosis complicated by fistulæ and abscesses; and, although he has not published any statistics on the basis of this new form of treatment, he believes that his results are still better. He has discarded the bandage entirely in these cases, using the cup exclusively for five minutes, allowing a rest of three minutes; again, suction for five minutes, and so on, for forty-five minutes altogether in the beginning of the treatment. This is continued daily until the flabby, pale granulations have been changed into hard, red granulations; then every second or third day, or the fifth day, suction is applied.

My personal experience with Bier's treatment of tuberculous joint diseases is limited to this form of treatment, that is, with suction apparatus. During my stay in Bonn it was my good fortune to see, among others, a middle-aged woman, who was to be discharged after several months' treatment with the small suction apparatus, on account of tuberculosis of the elbow joint. I ascertained that she had had two fistulæ, one focus being located at the lateral condyle of the humerus, the other corresponding to the head of the radius. The result was most astonishing to me and to Dr. Binnie of Kansas City. The function was perfect, and there was no swelling to be seen; in fact, no apparent difference between the two elbow joints. Two small, round, firm scars, brown-discolored, each one corresponding to a former fistula, reminded one of a most obnoxious form of joint and bone affection.

Spina ventosa must be spoken of in a separate paragraph, in as far as the treatment mentioned so far has yielded poor results. Dr. Klapp had encouraging results in this most obstinate form of articular tuberculosis by applying hyperemia to the joint in one of his large suction apparatuses. I did not secure any of the very breakable large apparatuses, but they could be easily made by any mechanic out of a glass irrigator and a rubber cup fastened to the open top, while the nozzle could be attached to a rubber pipe and suction pump.

Now to the treatment of acute inflammations—septic wounds, phlegmons, lymphangitis, etc. It requires the courage of one's convictions to add, by the blood stasis to the swelling, which we are accustomed to combat. But the results in the hands of a surgeon, who understands the technique, are splendid. It is the passive form of hyperemia only which is applied, the hot air having given no results. Whereas in tuberculosis the stasis is carried on for one hour as a rule—never more than two or three hours—the acute inflammations require an application of twenty to twenty-two hours, or where a tender skin does not stand the bandage longer, for at least eight or ten hours. An enormous edema is often the consequence of the procedure. The discoloration of the whole limb is apt to frighten the inexperienced; but, according to Bier, the increased inflammation is a desired phase of the affection, and the fact that, when the septic condition is overcome the swelling subsides in spite o he constricting bandage, is very significant.

During the intermission between two treatments, the limb is elevated, to allow the edema to subside. It is usually impossible and not necessary to do away with the edema entirely, before the new stasis is begun. Abscesses have to be lanced, of course, and two or three hours afterwards the bandage is to be applied—not too near the inflamed area. But here, as in cold abscesses, large operations are saved to the patient. An exception is acute suppuration complicated with severe circulatory disturbances, in which cases extensive incisions are preferred. In cases of deep suppurative tendovaginitis, several small incisions are made in preference to one large incision, which is apt to interfere with the nutrition of the tendon, and allow the tendon to snap out of its sheath. Drainage is never used, the covering of the wound with gauze being sufficient. It is advisable to change the place of constriction, in order to avoid nutritive disturbances under the bandage. For tender skin, the appliance recommended by Henley, an inflated rubber tube, is sometimes preferable.

The weak points of the remedy in acute inflammations are its injury in an overdose and its futility if administered in homeopathic doses. Therefore Bier advises only experienced men to treat deep progressive phlegmonous inflammation or osteomyelitis by his method. Inexperienced men should begin and acquire experience on fresh acute inflammations of any kind, upon subacute cases of not a severe type, and gonorrheal or pyemic arthritis.

The most striking example of the stasis treatment in phlegmon of the arm, I saw in a young man of nineteen years, injured in some factory, who entered the so-called septic ward of the clinic in Bonn in September. After receiving tetanus serum in the preventive doses, stasis was resorted to, the wound being loosely covered. An abscess was opened on the second day; on the third day the temperature became normal, and the whole aspect of the process changed. Out of a deep phlegmonous inflammation had developed a mild form of inflammation, which led to rapid recovery.

Almost like a specific is the effect of stasis by the bandage in gonorrheal arthritis. Even those most severe forms of this affection, in which the tendons are involved, and which, as a rule, lead to a more or less stiff joint, give astonishing results. The early relief of the excruciating pains allows the early motion—one of the strong points of Bier's treatment. Only by a stasis of from twenty to twenty-two hours and a profuse edema of the limb are these remarkable results accomplished. Sometimes the technique in this affection is difficult. The bandage produces pain and has to be taken off temporarily for one hour; but, as a rule, the pain ceases as soon as the edema appears.

Suppurative arthritis of the nongonorrheal nature also gives good results after the aspiration

of pus. Early motions of the joints are necessary and they are well borne, since, as soon as edema is produced, relief comes to the suffering patient.

I have spoken of the treatment of fistulous cases of tuberculous joint disease by suction apparatus. This suction treatment has been applied with most gratifying results in cases of furuncle, carbuncle, bubo, acute abscesses, mastitis, infiltrations, infected fresh and old wounds, insect bites with infection, paronychia, etc.—all together in more than 600 cases. The application is often painful in acute cases, and has to be applied with care, a small amount of suction giving good results. Forty-five minutes, all together, in a day has been found the best average time of treatment. During that time, one applies five minutes' suction and allows three minutes' rest—the same as in cold abscesses. Furuncles are not incised, only the crust of the papule is removed, before the suction is applied. In carbuncles only abscesses require a small incision. Furuncles are cured by this procedure usually in five days; carbuncles, in from ten to fifteen days.

The suction treatment in acute cases of inflammation therefore competes with the stasis treatment by rubber bandage and has two advantages over the latter. It removes the pus, besides producing hyperemia, and is, even in the hands of the inexperienced, free from danger.

In regard to the active hyperemia or hot air treatment, I can be brief. Bier uses it extensively in chronic cases of non-infectious origin, especially in ankylosed joints due to chronic rheumatism or arthritis deformans or chronic gonorrhea. Everybody knows how unsatisfactory the results are in such cases by any treatment known. Bier believes that the active hyperemia or hot air treatment properly applied in such cases is superior to any other mode of treatment.

Very interesting to me was the way in which he treats scoliosis. From thirty to forty children are treated every day in an apparatus which enables the hyperemization of the back of the patients, six at a time, for twenty minutes, which treatment is followed by gymnastic work. The children all declare that they feel limbered up after the hot air treatment, and the final results are far better than those by massage and gymnasium work, as practised, for instance, in Breslau.

Bier treats fractures by active hyperemia. In radius fracture, after good reduction under control of the radiogram, the arm is put in a hot air apparatus from the first day on, and the relief from pain allows the early manipulation of the wrist. Only a mitella is worn, no splints being applied, since the fragments after proper reduction do not part except by force. In fracture of the malleolus, after reduction, an ambulatory plaster-of-Paris cast is applied, which is cut into an anterior and a posterior half on the tenth day. Now dislocation is not to be feared, and active movement of the ankle joint is done by the patient, while his foot is in the hot air apparatus. After each treatment the patient walks in his cast fastened to the leg with a bandage.

Other affections giving good results are edema after fracture, exudates of joints, hemarthrosis, neuralgia, neuritis, varicose veins, etc., etc.

Since October 24 I have tested Bier's treatment of blood stasis in a number of cases. A boy, eleven years old, was taken sick three weeks previously, with what appeared to be follicular tonsillitis and was treated by a physician in the usual way. The patient came to me with a temperature of 101°, enlarged left tonsil, and a swelling about the size of a hen's egg back of the ear, corresponding to the insertion of the sternocleidomastoid. A small pocket of pus in the left tonsil was opened, which gave considerable relief to the patient; but the swelling in the neck remained, and began to enlarge, until a hard infiltration appeared. The temperature was running between 101° and 102° with a pulse of a hundred.

On October 26, at my first call, Bier's neck rubber bandage was applied and kept on for twenty-one hours; the throat was treated and sprayed with a 50-per cent. solution of peroxide of hydrogen, and mouth and throat gargled with a warm saturated solution of boric acid. Within twenty minutes the patient told me that the bandage gave him relief; and after several hours of application he could move his head very much better, whereas before the slightest change of the position seemed painful. On the second day the bandage was applied tighter and an edema appeared on both sides of the face. The swelling in the neck assumed larger proportions and covered the whole neck and the occipital region of the scalp. On the fifth day of treatment, in narcosis, an incision of about one and one-half inches was made outside of the sternocleidomastoid, and carried down to the bone back of the mastoid process. About two teaspoonfuls of pus were evacuated, no scraping was done, no drainage applied; the wound was as usual covered with sterilized gauze. A few hours afterwards a good stasis by the rubber bandage was induced and kept up for twenty hours. After that, nothing but a change of dressings took place, and one week after the little operation the wound was perfectly closed. My impression of the case was that Bier's treatment had been of great assistance to me, in so far as it shortened the duration of the affection and localized this rather serious form of cellulitis. Undoubtedly it saved the patient a larger incision, and the after-treatment was exceedingly humane.

Of the other patients treated I want to mention a little boy, ten years old, who suffered from a very painful attack of nonsuppurative otitis media on the right side. The rubber bandage applied to the neck below the larynx relieved him soon after application; and when the mother, at bedtime, removed it, for fear it might do him harm, the intelligent little chap asked to have the bandage put on again.

A case of tuberculous orchitis is under my treatment at present. I use the cup every second day, and have taught the patient—a man of sixty-two years—to apply the bandage himself for three hours every afternoon. I believe the patient does it correctly, from the description he gives me, and from the way he made the application himself under my control in my office. Since the treatment has to be carried on for several months I am not in a position to-day to tell you anything about the result; but after eight treatments in my office with the suction apparatus the purulent discharge has changed into serum.

33 Allen Street.

Relief of Itching by the Use of Pilocarpine.—Pilocarpine in doses of one-fourth grain is of great value in different forms of pruritus, such as the general pruritus of jaundice, the localized pruritus of urticaria, and the pruritus so common in old people. Give one-fourth grain of pilocarpine by the mouth, best at night.—J. J. Reid.

CHRONIC AND PERIODIC VOMITING.*

By DUDLEY ROBERTS, M.D.,

BROOKLYN.

ASSOCIATE VISITING PHYSICIAN, BROOKLYN HOSPITAL.

The difficulties attending the diagnosis of the causation of vomiting are readily accounted for by the great extent of the nerve tracts and the connections of the center that controls this complex act. We must conceive of this medullary center as being susceptible of stimulation not only by direct irritation and by sensations from the higher nervous centers and the stomach, but also through any of the afferent nerves of the body. The effect that such afferent impulses will have on the vomiting center is largely conditioned by the peculiar constitution of the individual's higher nervous system; in some individuals any slight pain or unpleasant sight induces nausea or vomiting, while in others such a result is not noticed although the irritation be very severe.

In studying a case of vomiting we are very largely dependent on related phenomena for an explanation of the cause and site of excitation; while the act itself presents differences in severity, repetition, and amount of accompanying nausea, the other facts of life and symptoms may be essential in the diagnosis. While a complete differential diagnosis of the conditions that can cause chronic and periodic vomiting would be impracticable, we would review the conditions that may give rise to these types and discuss whatever characteristics the vomiting may have.

As one of the first steps in the diagnosis of an obscure case of vomiting is the elimination of a gastric cause, a discussion of the few gastric diseases that may cause these forms is of primary importance.

Acute gastritis occasions vomiting that is more or less severe during the first twenty-four hours of the disease, and usually the condition is appreciated from the history of exciting cause, the general picture of the disease, the slight gastric tenderness, the more or less constant nausea, the complete anorexia, and the inability of the stomach to retain anything. Occasionally vomiting of a protracted nature may be caused by an acute gastritis and the condition is confusing if not seen from the inception. These are usually the cases where there has been no treatment or an improper one. Vomiting continues, food is held in the stomach only a very short time; the pain in these conditions is but slight. Such cases may result in starvation and death. The character of the vomitus distinguishes these cases from those in which vomiting results an equally short time after food ingestion.

Chronis gastritis is still considered by some a proper diagnosis when nothing except a slight subacidity or superacidity is found objectively to account for subjective gastric complaints. There is, however, a growing tendency to demand more positive evidence. While many textbooks speak of vomiting as a common symptom of chronic gastritis, Lockwood,[1] from an analysis of a large series of cases, found that vomiting was never present in uncomplicated non-alcoholic gastritis. Personally I am of the opinion that vomiting in a case of chronic catarrh indicates either that the stomach has been overloaded or that an acute catarrh has been instituted, or that the pylorus has become narrowed and muscular insufficiency has resulted. Unless one of these conditions be in evidence, a further search for the cause of the vomiting is indicated.

In ulcer of the stomach chronic vomiting is unquestionably a very common symptom, but the exact frequency is not agreed upon. Howard[2] speaks of vomiting as the commonest symptom, present in 85 per cent. of the cases admitted to the wards of the Johns Hopkins Hospital. Wirsing[5] from an analysis of 320 cases concludes that vomiting is present in 60 per cent. Speaking of chronic ulcers, Mayo says that vomiting is a late symptom due to interference with the passage of food. In the acute ulcers there is a general agreement that vomiting usually occurs at the height of a paroxysm of epigastralgia, one-half to three hours after the ingestion of food. The relation of the vomiting to the pain has seemed to me rather distinctive; there is a gradual development of the pain, and at its height vomiting results with very little nausea. After the vomiting the pain rather quickly subsides and does not recur until more food is ingested. The continuance of the pain after the vomiting indicates the nearness of the ulcer to the pylorus.

With reference to the vomitus it is interesting to note the divergence of the present opinion of clinicians from that formerly held in regard to the frequency of superacidity found in ulcer. Ewald[3] gives the frequency at 45 per cent. and states that over 9 per cent. had subacidity; Wirsing, superacidity, 47 per cent., and subacidity, 2 per cent.; Wagner,[6] superacidity, 42 per cent., and 10 per cent. subacidity; Howard,[2] only 27 per cent. superacidity and 47 per cent. subacidity. There is a rather general agreement that in only about 10 per cent. of the cases of vomiting from ulcer is blood entirely absent from the vomitus at all times.

In hyperchlorhydria without organic basis vomiting is a rare symptom, according to Riegel.[7] Hyperchlorhydria with attacks of vomiting, or chronic vomiting is an indication of ulcerative lesion or a complicating condition of some sort causing vomiting. Certainly enough cases of marked hyperchlorhydria are seen to indicate that the mucosa is not particularly sensitive to increases in the usual degree of free acidity.

In the intermittent form of Reichman's disease, gastrosuccorrhea periodica, vomiting is a most pronounced feature of the condition. This neurosis is characterized by recurring attacks of vomiting that usually come on during the night; there is commonly a rapid development of more or less severe gastric distress and the vomiting of gastric juice in considerable amounts. At first there may be vomiting of food remains, but in a short while more fluid, found to be true gastric juice, of normal or supernormal acidity, is vomited. The condition continues for a few hours to several days. There may be hypersecretion between the attacks or normal secretion and no dyspeptic complaints. There is much variation in the amount of pain in these attacks; one case under observation for the past four years complains of no actual pain during some of the attacks.

Chronic gastrosuccorrhea rarely produces vomiting unless induced by organic lesions. Cases have been under observation by the writer for several years that showed 200 c.c. to 400 c.c. of clear gastric juice from ten to fifteen hours after a meal; while such cases have shown atony there has been no evidence of pyloric obstruction, a test dinner being disposed of in but little more than the normal time. When vomiting is a symptom of a case showing hypersecretion there is sufficient justification for the suspicion that an ulcerative lesion or pyloric obstruction is present.

"Muscular insufficiency" of the first degree, atony of the stomach, does not produce vomiting. Although the stomach takes an abnormal time to perform its muscular function, one meal is passed on before the next is added. In the more severe degree

* Read before the Society of Alumni of Bellevue Hospital.

of insufficiency—dilatation due to mechanical interference with the passage of the contents—the vomiting is one of the chief features and almost pathognomonic in its nature. Such obstructions to the passage of food have a number of causes in both stomach and duodenum and the course and other symptoms will depend on the particular cause. Usually the condition is developed gradually and the peculiar vomiting that it gives rise to may be overlooked. The vomiting may be preceded by actual pain, if the lesion be ulcerative, or by merely an uneasiness of the stomach; generally there is little nausea. The important point in distinction is the copious vomiting, considerably more being vomited than should be left in the stomach. Vomiting of food, ten or more hours after its ingestion, indicates a muscular insufficiency; temporary insufficiency may result from severe emotional disturbances, marked overloading of the organ, or acute inflammation; frequent repetitions of this act indicate a permanent condition, and thorough tests of the ability of the stomach to empty itself should be made.

In carcinoma of the stomach vomiting is said to be an early symptom by some medical writers, but this statement is contradicted by the abdominal surgeons. Riegel states that vomiting is a rare symptom in carcinoma of the stomach unless one of the orifices be interfered with. Occasionally there is a very persistent form of vomiting seen early in carcinoma that is due to a complicating acute gastritis. Carcinomata at the orifices inducing vomiting may undergo degeneration, and the vomiting may then cease.

Stenosis of the cardia, or low lying stricture of the esophagus, whether malignant or benign, occasions regurgitation, and this is usually spoken of as vomiting; when there is dilatation of the esophagus above the stricture there may be an act more closely resembling vomiting, but with little nausea. The vomitus may amount to considerably over a pint and thus be the cause of confusion if the stomach sound is not used.

Gastroptosis of itself very rarely presents the symptoms under discussion; the rare instances are due to some complicating neurosis or to a complicating or induced muscular insufficiency.

Hernia of the linea alba is one of the more rare conditions that may be the cause of vomiting in association with pain at the time of peristaltic activity or especial bodily movements. Unless these small tumors be searched for the condition at times may cause confusion.

From a view of the gastric diseases it is evident that the number causing chronic or periodic vomiting is very small. In any case of vomiting, if acute inflammation, ulcer, periodic hypersecretion, and interference with the orifices can be excluded, the cause of the vomiting must be searched for elsewhere.

In the course of ordinary nervous dyspepsia there may be occasional nausea, and vomiting may at times result, but such an occurrence usually follows some especial inciting cause. In a recent publication Mathieu and Roux,[8] in discussing the under-nourishment in certain dyspeptics and neurasthenics, describe the late afternoon nausea seen in these patients, particularly young women, as a perversion of hunger; if the condition is not recognized and the starvation corrected there may be instituted a true nervous or hysterical vomiting.

While at the menstrual epoch disturbances of the stomach are very common, in certain young and anemic women, and women who flow excessively at this time, there is not infrequently observed a more or less constant nausea and morning retching that is apt to continue for several days after recovery from the physiological process.

Nervous or hysterical vomiting presents characteristics that warrant its separation from other forms of vomiting, although the line of demarcation is indefinite. Usually these cases are seen to be women, the condition being developed at puberty or the climateric because of some severe emotional strain or accident. Behind such exciting causes there is always a certain psychopathic taint. In a typical case of this nature the vomiting occurs either in the night, in the morning before breakfast, or very shortly after meals. The points that Stiller[9] has emphasized in regard to this condition are the slight nausea, the ability of these patients to retain irritating foods at times while the blandest foods are rejected, the failure to grow thin, and the great suggestibility from within and without. Such patients may die of starvation, but instances are rare.

While all vomiting except that due to centric irritation of a direct nature, or induced by sensations from the higher parts of the brain must be considered reflex, it is convenient to limit the term "reflex vomiting" to that due to irritation outside the direct nerve tracts. In these cases there is probably a certain weakness of the nervous system unless the irritated part is close in its nervous connection with the direct nerve tract from stomach to center. For example, when vomiting results from irritation of the gall-bladder, pancreas, or intestines there need be no premise of a nervous weakness exaggerating or failing to inhibit the afferent impulse.

In diseases of the intestine the likelihood of vomiting resulting from irritation decreases rapidly from the pylorus down. According to the statistics collected by Hemmeter[10] about 20 per cent. of the duodenal ulcerations cause vomiting. Ulcerations lower down in the intestines rarely present this symptom unless stenosis is caused or peritonitis is set up. In the acute catarrhal diseases of the intestine vomiting may be a prominent symptom during the toxic stage: after that it is uncommon. In the severe cases of colitis even with ulceration there is rarely vomiting after the first few days, when the toxemia is great.

Chronic stenosis of the duodenum shows itself in a similar way to stenosis of the pylorus. A lesion below the papilla will cause the presence of considerable amounts of bile in the vomitus. Stricture of the lower intestine, even of the lower sigmoid, may cause attacks of vomiting, as seen in one case by the writer. Referring to stenosis of the colon, Hemmeter says that he has never observed a case of simple constipation in which vomiting was a repeated symptom; he is inclined to attach considerable importance to such attacks if they occur in association with constipation and abdominal colics. Boas,[11] discussing the same subject, says that vomiting is an undervalued symptom, recurring as it does with intestinal colic; while not characteristic, it is an extremely rare manifestation in the more common stercoraceous flatulency.

The chronic peritoneal inflammations usually do not cause vomiting unless they produce stenosis of the intestine, deformities of the pylorus, or strongly drag on the stomach during peristalsis. Such a "perigastritis" may be the cause of attacks of gastric pain and vomiting at the height of digestion.

The close relationship between the gall-bladder and the stomach readily explains the commonness of vomiting at the time of a gall-bladder colic. Such attacks are not, as a rule, of long duration, very frequently occur at night, and are associated with marked tenderness of the gall-bladder. In addition

to vomiting occurring at the time of colics, inflammation of the gall-bladder may occasion attacks of pain of moderate severity occasionally accompanied with vomiting.[12] In these cases there is usually a history of gall-bladder disease to suggest the true nature of the condition, and there is the absence of hematemesis and melena.

The pregnant uterus is very possibly the most common cause of morning nausea and retching, yet very frequently overlooked. The vomiting of pregnancy is, no doubt, as Williams[13] has shown, either reflex toxemic or hysterical.

The displacements and inflammatory enlargements of the uterus are very common causes of faintness and nausea in association with uterine symptoms. Prolonged standing may occasion considerable afternoon nausea, and, in the neurasthenic, vomiting may result.

Nausea and other dyspeptic complaints may be due to the irritation developed by disease of the male sexual organs. Such cases are usually observed in the sexual neurasthenics. Conheim[14] reports the case of a middle-aged man, with severe vomiting, who, on examination, was found to have a normal stomach, but a much dilated urinary bladder, the result of a hypertrophied prostate; the cure of the latter conditions stopped the vomiting. Cases of this sort are not uncommon in women during and after pregnancy.

Severe kidney colics are accompanied by vomiting in some instances at the time of the paroxysm of pain; otherwise the surgical lesions do not produce this symptom. The movable kidneys have occasionally been described as causing exceedingly persistent vomiting, the condition being cured by operation;[15] such a result is uncommon, but nausea as a symptom of movable kidneys is quite frequently seen, especially as an occurrence of the late afternoon, owing to prolonged standing on the feet.

Pharyngeal abnormalities not infrequently are responsible for morning nausea not only in alcoholics and smokers, but as well in those not addicted to any such indulgence; such a condition seems to result from the swallowing of mucus or the irritation of the retropharynx. Usually there is a pharyngeal cough, or other evidence of the local condition. Elongation persistent vomiting, and not always are there symptoms of throat irritation. Such a case came to my attention, death being narrowly averted by ablation of the uvula.

Diseases of the lungs and bronchi very commonly cause vomiting when the amount of mucous swallowed is large. In adults of the gouty or plethoric type there may be reflex vomiting from severe congestion of the bronchi; this may occur independently of attacks of coughing.

Cardiac conditions attended with loss of compensation and late cirrhosis of the liver very commonly cause vomiting due to passive congestion: in the latter condition particularly there may be considerable hematemesis, but the morbid lesion is distinguished from ulcer by the comparative absence of pain. Early in cirrhosis the vomiting is attributable to the coincident pharyngitis from alcohol.

Vomiting in association with prolonged attacks of general or unilateral headache are usually described as migrainous attacks, "bilious attacks," or "sick headaches." Certain ophthalmologists would attribute all such attacks to eyestrain. Walton,[16] after a careful study of the headaches in the congenitally blind, concludes that a sufficient number were afflicted with migrainous attacks to preclude the supposition that all such cases are due to eyestrain. While the majority of cases suffering from these attacks are due to eyestrain, there are not a few that follow dietary indiscretions in certain families, in whom no eyestrain can be determined, and also cases in anemic young women that seem to follow several days of constipation, treatment of the latter condition curing the attacks. Vomiting from eyestrain is usually a sequence of severe headache, and generally occurs after the eyes have been over-used—in reading, sewing, or travel in cars.

Vomiting due to reflex from the ear is rarely seen except in sudden attacks, associated with deafness, vertigo, and tinnitus, the syndrome first described by Ménière as characteristic of labyrinthine disease. It is now realized that the same conditions may result from pressure in the middle, or even external, ear. The local treatment of the ear does not commonly succeed in curing these attacks, and it would seem that in many instances there was an underlying constitutional trouble to account for the condition. In several of these cases that have come under the writer's observation there was discovered a secondary gastric atony with subacidity. In one such case the patient would vomit nearly a quart of mucous fluid during the first few hours of an attack. In this case sodium bromide would prevent the attack, if taken on the first suggestion of vertigo. As observed by the writer, these cases vomit as a sequel to very severe nausea, apparently caused by the vertigo; if the vertigo is stopped by the recumbent posture the nausea ceases. Recently a case was seen in which an erythema multiformi appeared to be responsible for the attacks; three years ago a young woman began to suffer from suddenly developed swellings of the face of very pruritic and burning nature. Soon after their first appearance in one of the attacks she began to have the typical Ménière's syndrome. These attacks continued, in spite of treatment, until a few weeks ago, there being an apparent association of the erythema and ear disturbance. Treatment of the gastrointestinal canal has improved the erythema and only moderate deafness is complained of.[17]

A similar case was reported by M. Sugar, but in his case there was a purpuric eruption, the ear symptoms and obstinate vomiting coming and going with the purpuric rash.

The gastric crises seen in tabes dorsalis, and in other spinal cord affections, such as myelitis and syphilis of the cord, multiple sclerosis, and also in Basedow's disease, may be the cause of serious diagnostic errors. In tabes the crises occur in the preataxic stage of the disease and may be the first subjective complaint. Fortunately, there are always some of the objective symptoms to be found. Occasionally the attacks are preceded by nausea, but usually these attacks begin very suddenly, the patient being taken with severe tearing pain in the epigastrium and precordium, and soon hard, painful vomiting; there may be headache and pains in the limbs; usually the abdomen is retracted and constipation obstinate during the attack, which lasts from a few hours to a few days. The attack usually terminates abruptly, only the soreness of the abdominal muscles being left; the patient can usually take food at once.

The vomitus is in no way characteristic; in some cases there may be small amounts of blood; Ewald[18] reports 4 cases of hematemesis in his 89 observed cases. The amount of pain in these crises is somewhat variable; in a case seen by the writer there was no complaint of pain, but only of attacks of vomiting; on questioning, pain was admitted during some of the attacks.

The case cited by Werner[19] shows what serious errors these attacks may cause. For attacks of vomiting and epigastric distress a woman was operated on by the gynecologists, the cervix being cau-

terized; later an abdominal surgeon of note performed a gastroenterostomy for a supposed gastric ulcer; and the attacks still continuing the uterus and appendages were removed. It happened some months later that the attacks ceased and the ataxic symptoms developed.

Closely resembling these spinal-cord crises are the attacks of primary nervous vomiting first described by von Leyden,[20] and since that time discussed by a number of observers. There is the sudden onset of attacks of vomiting with or without epigastric distress, independent of food ingestion; there are the severe nausea, the temporary prostration, the retraction of the abdomen, the obstipation during the attack. Everything taken into the stomach for hours or days is vomited at once. Autopsies in such cases have failed to show the causative lesion. The attacks differ from those of cord lesions in that they tend to recur at approximately the same intervals, or to become less frequent, sometimes to cease entirely.

"Juvenile vomiting" is a condition of mixed causation. The name is given to attacks of vomiting in anemic school children between the ages of 8 and 14. It may be an affection of the hour before school, being due to a nervous dread for some particular reason. Again, it may be an affection of the hours after school, and then very probably be attributable to eyestrain. Conheim[14] says that any one of the three common intestinal worms in the intestinal tract may act as the exciting cause, and he advises a careful search of the stools after a vermifuge has been given in any case of unaccountable vomiting in children.

The affection of children variously denoted as cyclic,[21] periodic,[22] recurrent, or persistent[23] vomiting, has reference to a class of cases described by these names, there being nothing distinctive to account for the attacks. In many ways these attacks resemble the crisis already discussed, the independence of the kind of food, the suddenness of the attacks, the severity and long continuance of the vomiting, the retraction of the abdomen, and the constipation. Edsall, Marfan,[24] and others have emphasized the acetonemic features of the condition. Snow[25] has shown that in some there is a hypersecretion of gastric juice. Rachford[26] points out the association of such attacks with migraine. Osler,[27] in discussing the abdominal symptoms associated with the erythemas, states his belief that certain cases of recurrent vomiting in children are due to one of these erythematous diseases.

In diseases of the central nervous system vomiting may be a very important part of the picture. In acute meningeal disease this may be the most pronounced feature of the invasion and be exceedingly persistent throughout. In chronic meningitis, cerebral abscesses and tumors, dilatations of the ventricles, and hemorrhage vomiting may be very prominent. While in these conditions there is nothing absolutely characteristic, certain features are suggestive such as the suddenness of the attack, the slight nausea, and the severe or violent vomiting, the lack of all relation to the ingestion of food, the independence of emotional states, the semi-consciousness or unconsciousness of the patient during an attack, and the effect of changes of position.

While vomiting may occur in the course of any disease, attacks may be caused by certain constitutional diseases, particularly gout, nephritis, diabetes mellitus, Addison's disease, malaria, anemia, and the erythemas.

Cases of irregular gout are described in which severe vomiting occurs, but such cases are suspicious, especially when associated with abdominal pain. When the individual has had previous attacks of regular gout such a diagnosis might be justified, but in one case seen by the writer such a diagnosis was contradicted later by the appearance of unmistakable gall-bladder troubles.

In nephritis vomiting is a regular symptom when uremia is well developed, but occasionally it may be one of the first manifestations; usually there is morning nausea and retching in these cases, and later the appearance of these complaints through the day.

In diabetes mellitus vomiting occurs only as a late symptom, shortly preceding some such manifestation of acid intoxication as coma.

Vomiting from Addison's disease also occurs late, and then may be seen in association with vertigo, tinnitus and headache, not, however, in the form of attacks such as characterize ear conditions.

Malaria causing periodic or chronic vomiting is rarely observed, except in the very severe forms and the chronic forms with "caked" spleen; usually in these cases there is hematemesis. In the acute cases there is generally severe pain at the time of the vomiting, but the condition is readily diagnosed by examination of the spleen and blood.

In the various anemias vomiting is not an uncommon symptom. Frequently this is a result of undernourishment as discussed above, being an exaggeration of nausea due to hunger. In the more severe grades of the simple anemias and the pernicious forms vomiting may be a pronounced feature. Usually in these cases there is more or less hematemesis, but the vomiting does not bear the intimate relation to food ingestion as happens in peptic ulcer nor is there severe epigastric pain. The possibility of induced ulceration is always to be considered.

In that general class of cases that may be designated by the term "erythematous" diseases, including the angioneurotic edemas, the circumscribed edemas, the puerpuras, the erythemas, and uriticaria, there may be severe abdominal symptoms and persistent vomiting. In one case seen by the writer the rash did not appear until there had been several days of persistent vomiting, abdominal pain, constipation, and melena. Osler reports many such cases.

Chronic lead poisoning with attacks of colic occasionally may be the cause of persistent chronic vomiting.

A consideration of this survey shows the difficulties that may attend the diagnosis of causation in chronic and periodic vomiting; careful search of the entire body and its functions may be necessary. While the possibilities of variation are great, we would offer certain deductions from this survey, having reference particularly to the characteristics of the vomiting that may be expected in certain conditions.

1. Vomiting of a chronic type, following a gradually developed epigastralgia, one-half to three hours after the ingestion of food, is attributable to peptic ulcer, gastric or duodenal.

2. Chronic vomiting that occurs ten to fifteen minutes after food ingestion is attributable to stenosis of the cardia, nervous abnormality, cerebral lesion (occasional rather than chronic), or to protracted acute gastritis.

3. Copious vomiting ten or more hours after food ingestion indicates a muscular insufficiency; frequent repetition indicates a permanent lesion in the nature of a mechanical interference with the exit of food.

4. Vomiting in the night is particularly liable to occur in choelithiasis, periodic hypersecretion, muscular insufficiency, and nervous abnormality.

5. Vomiting attempts when the stomach is empty

indicates a cause other than a gastric lesion, either a reflex, a toxemia, a cerebral lesion, or a nervous abnormality.

6. Morning nausea and retching indicate either a beginning of pregnancy, alcoholism, pharyngitis, nephritis, or a nervous abnormality.

7. Periodic vomiting of clear gastric juice of normal or supernormal acidity in any considerable amounts indicates a secretory neurosis or an ulcerative lesion.

8. Vomiting as a sequel of headache, accompanied by severe nausea, but no gastric or abdominal symptoms, characterizes attacks of migraine; in a majority of cases eyestrain is the underlying cause.

9. Attacks of vomiting of sudden onset, with tinnitus, deafness, and vertigo, are attributable to disturbances of pressure in the internal or middle ear.

10. Periodic attacks of vomiting of sudden onset, associated with more or less severe gastric pain and nausea, retraction of the abdomen, obstinate constipation during but not preceding the attack, and freedom from abdominal tenderness, are suggestive of the spinal crises, idiopathic nervous vomiting, and lead poisoning.

11. Periodic attacks of vomiting after abdominal colic and constipation, with localized or general tympany, are suggestive of chronic intestinal stenosis.

84 Remsen Street.

The Doctor's Lamp.—A correspondent writes to complain that there is in his village a medical practitioner who served for a year as a civil surgeon in the late South African war. Since his return home this gentleman has put up a white lamp with two red crosses in front of his house, which emblem is taken by the simple village folk to indicate some special privilege. Professional opinion runs strongly against any form of advertisement, and so conspicuous a lamp would certainly appear to fall within the meaning of that term.—*British Medical Journal.*

THE ETIOLOGY OF ECZEMA.*

By JAMES C. McGUIRE, M.D.,

WASHINGTON, D. C.

PROFESSOR OF DERMATOLOGY, GEORGETOWN MEDICAL COLLEGE; DERMATOLOGIST TO THE GEORGETOWN HOSPITAL; CONSULTANT TO THE CASUALTY HOSPITAL, ETC.

"Who shall decide when doctors disagree,
And soundest casuists doubt like you and me."

It is axiomatic that physicians *will* differ, and it cannot be better illustrated than in their conclusions in regard to the causes of diseases. You are no sooner convinced that you fully appreciate the nature of a certain malady than you are confronted with an entirely different conclusion by some accepted authority; so that eventually you are forced to the conclusion that you know little or nothing of the *essential* cause of any disease, except those in which a specific microorganism is clearly shown to be present. In this paper I will confine my remarks to the etiology of eczema. What do we mean by eczema? Is it a disease or only a name? A word derived from the Greek, meaning to boil over, to effervesce, or literally an eruption. It is not referred to in the writings of Hippocrates, Galen or Calsus. The first mention of it, according to Hebra, was by Ætus, A. D. 513, but it remained for the English dermatologist, Willian, to first partially describe the disease as we now understand it. Dr. Nevins Hyde refers to the word as being so frequently used by the advertiser, the charlatan, that there are few experts who now use it without a species of mental reservation or qualification, adding that in his opinion the doom of the word is probably written. When Professor Walker of the Royal College of Physicians, Edinburgh, gave his definition, he probably had in mind John Hunter's remarks that "definitions are damnable things," for he says, "without sarcasm," it is "a term commonly applied to any wet or scaly inflammation of the skin, of the nature or cause of which the observer is ignorant."

In defining a disease we should be careful in the use of the terms that we are to apply to its different forms and stages. There are many designations used in connection with eczema that are not only misappropriate and absurd, but are seriously misleading. Though we may use the terms papular, vesicular, pustular, squamous, to designate the preponderating or only lesions present, we should not refer to the malady as scrofulous or tuberculous, as is so frequently done, for this would naturally suggest the idea of the existence of tubercle bacilli, whereas it is simply meant there is a resemblance to the symptoms that occur in those diseases in which this microorganism is actually present. So it is with psoriatic, syphilitic, ichthyotic eczema, which have entirely different pathological conditions: though they may occur in the same individual they are not combined. Seborrheal eczema is justified, as the two pathological conditions manifest themselves as one disease. Many cutaneous troubles, such as scabies, eczema-marginatum, impetigo contagiosa were formerly classified as eczematous till the parasites that caused them were actually demonstrated. There is no doubt that in the near future other cutaneous manifestations now appearing as eczema will be proven to be due to specific bacteria. Old theories—long ago condemned as absurd—occasionally crop up again and are seriously discussed. I have always taught my students and emphasized the fact that we should cure an eczema as quickly as possible. Professor Hebra, known as "the father

*Read before the Medical Society of the District of Columbia, November 28, 1905.

of dermatology," has said, "The object of our warmest endeavors is to find a means of terminating these diseases (skin diseases in general) as speedily as possible. Were we only in possession of remedies which produced cures thus rapidly we should have no anxiety with regard to the appearance, from this cause, of metastasis or of any other consecutive diseases." And again Malcom Morris of London declares "The fear of curing eczema on account of causing congestion of the brain or other internal disorders" as being absolutely without foundation. Yet we find the well-known dermatologist, Brocq of Paris, strongly advises against curing some forms of eczema too quickly. He says, "It occasionally occurs that the disappearance of an eczema is followed by visceral troubles of the gravest nature; that in rare cases serious cerebral accidents may follow the cure of chronic eczema."

In studying the literature pertaining to eczema we find many pages devoted to the predisposing causes from within, and the exciting causes from without. Though predisposing and internal causes are used as synonymous terms as are external and exciting, we may frequently find the reverse to be true. As to so-called constitutional causes, we find the etiological factors given as—to mention only a few—asthma, diabetes, onstipation, diarrhea, anemia, chlorosis, malaria, "want of tone of the nervous system," neurasthenia, "taking cold," disorders of digestion and assimilation, vaccination, adherent prepuce, intestinal parasites, uterine disorders, dentition, diseases of the liver and kidney, improper food, dyspepsia, pregnancy, lactation, menopause, different diatheses, such as gouty, rheumatic, hepatic, lithemic, dartrous assimilative debility, and a few others. There is no exaggeration in this list; they may be found in any text-book. For some unaccountable reason cancer of the stomach, locomotor ataxia, and cholera are omitted. In fact, "any old" cause is given that may occur to the vivid imagination of the author. It is amusing to note that frequently the very same diseases, or conditions that are referred to as causative, are given as curative or preventative: such as vaccination, pregnancy, and lactation.

If these constitutional conditions are to be regarded as the predisposing causes we should expect to find them associated with at least the majority of cases of eczema, but let us see if a true relationship can be proven. It would be indeed odd if some one or more of these disturbances were not present in a given case, but I contend it does not occur more frequently in ezcema than in many other cutaneous maladies. When they do exist and the cutaneous conditions vary with their relapse and improvement it simply points to the fact that the eczema is better or worse, according to the strength of the patient to resist the disease. In fact, it would appear impossible for such varying pathological conditions to give rise to a catarrh of the skin; the coexistence of the several conditions is simply a coincidence. In reviewing the predisposing causes we find that some favored observers have discovered actual changes in the nerve structures; this would be worthy of consideration, but that it has been seen so seldom it can only be regarded as a coincidence. The influence of the nervous system has been well stated in a short monograph by the eminent dermatologist, Dr. L. Duncan Bulkley of New York, and no one in this country, at least, is better qualified to pass an opinion upon any question pertaining to skin diseases in general. In the paper referred to he gives an analysis of ten thousand cases of miscellaneous skin diseases occurring in his private practice. Of these, 3,201 were sufferers from eczema (32.01 per cent. of the whole number), thus bearing out the generally accepted statement that one-third of all skin diseases—as they are presented to the practitioner for treatment—are eczematous. In reviewing his tabulation of six thousand cases of eczema, it is found that the disease is most frequent between the ages of twenty and forty—when the strain of life is the greatest (one-third of the entire number). Among the various forms of nerve disturbances he mentions neurasthenia, nervous shock, reflex phenomena, and functional and structural changes in the nerves themselves. Later I will give a clinical account of several such cases that have come under my observation.

I do not believe that gout, rheumatism, and many other of the diseases refered to as predisposing factors have anything whatever to do with either causing the disease or influencing it in any way after it has been established, except so far as any so-called "run-down condition" of the general system may render the cuticle less resistant to irritation. Diathesis in dermatology means a general constitutional condition which predisposes to or is accompanied by cutaneous disturbances. The idea originated with the French dermatologist Biett, in 1833; he was able to trace certain skin manifestations to syphilis, thus leading Casenove and others to attempt to elaborate the theory, so as to trace all forms of cutaneous diseases to some specific constitutional condition. Hence arose the terms scrofulous, tuberculous, arthritic herpetic, and other diatheses. Prof. Piffard of New York is a firm believer in this theory, and he suggested the name rheumic, as a condition due to the accumulation in the blood of an excess of certain excrementitious substances (the same that are efficient in the causation of gout and rheumatism); but with few exceptions the whole theory is now discarded by English, American, and German specialists. Pye-Smith of Edinburgh University rejects the whole doctrine and says "it seriously impairs the advance of general medicine"—that the hypothesis is practically misleading in prognosis and treatment, no less than scientifically unsound."

Heredity.—Though no child was ever born with eczema, many are brought into the world with a vulnerable skin, that may later develop the disease under certain circumstances. The cuticle is not "eczematous," but is particularly susceptible to different inflammations, varying according to the form and degree of irritations, and the constitutional conditions, the age, sex, nationality, and many other factors. But with very few exceptions it has not been within my personal experience to be able to trace the disease to the progenitors. So that my own opinion is that, as a rule, eczema cannot be regarded as hereditary, either directly or indirectly; that is, that the malady is no more likely to occur in those children whose parents were suffering with the disease than those whose progenitors had a perfectly normal cuticle. According to Kaposi, who was the representative treacher of the German school of dermatology, "all the different forms of eczema can always be produced artificially in all parts of the skin, in every individual." Prof. Nevins Hyde of Chicago is in accord with these views. He has declared that "every phase of eczema can be artificially produced by the action

of external irritants." The majority of English and American dermatologists take issue with these eminent specialists, and make a distinction between a simple artificial dermatitis and eczema. As Prof. Hardaway says, "An eczema is a dermatitis, but a dermatitis is not necessarily an eczema." An example may be given in the inflammation produced by the hus toxicodendron and by the aniline dyes. There is at first a dermatitis, and it may end as such or it may continue, or frequently recur as an eczema. According to Jamison, Leloir, Hardaway, and others, when the inflammation returns year after year it is caused by other exposures to the poison; if this dermatitis is sufficiently prolonged a true eczema may develop. Pye-Smith makes the distinction between a traumatic dermatitis and an idiopathic eczema. He says: "When the irritation directly follows the irritant, is not prolonged after its cessation, does not spread to other than the affected regions, does not recur without fresh irritation, and does not follow the local distribution of eczema, then it is best to call it a common superficial dermatitis of traumatic origin." According to Malcom Morris of London, "A dermatitis appears in response to a visible cause and begins to disappear when that cause ceases to operate. True eczema arises without obvious cause, and the skin may be healthy, or there may be some preexisting abnormal condition, but there is no visible source of irritation." Jamison declares, in regard to the generally described cases of dermatitis, "that if it is not eczema it closely resembles it in many particulars."

At the present time American dermatologists, as a rule, consider that the truth as to the etiology of eczema lies midway between the teachings of the French and German schools; that is, that the affection arises in consequence of some unknown constitutional condition, and is brought into evidence in consequence of some external irritant acting upon a vulnerable skin. (Refer to Walker's definition above.)

Is the Disease Contagious?—The consensus of opinion is that it is neither contagious nor autoinoculable, notwithstanding the fact that so eminent an authority as Professor Unna of Hamburgh classifies several of the forms of the malady as infectious catarrhal inflammations, but even he does not at present claim a universally parasitic origin of the disease. The peculiar bacteria that cause the vesicular and seborrheal eczemas he designates as the morococci, from their resemblance to clusters of mulberries. He has succeeded in producing the disease by inoculation, the morococci and the toxins produced by them acting on a susceptible skin. Jamison, Leloir, and others, while doubting that this or other parasites are the essential cause of the disease, consider they play an important part in perpetuating the trouble after it has once been established. As to its autoinoculability, it has been observed at times that the eruption will spread when the discharge runs down upon the previously unaffected skin. Jamison believes that this discharge may even affect other individuals who come in contact with it. Van Harlengen does not believe the disease can spread or be conveyed in this way. He says: "It cannot be acquired from being in contact with or handling the discharges." It is explained that, when the contiguous surfaces become affected, it is simply from the action of the original cause, or as a result of the heat and moisture and the rough character of the adjacent skin, acting as a simple irritant; the discharge itself is only contagious in the sense that all pus is more or less infectious. There is no question but that the parasitic theory is growing well in the minds of those who formerly argued against it, because they could not always find the bacteria in the initial lesions, for Bender, Brockhart, and others have now proven that the toxins alone, of the staphylococci, for instance, can produce vesicles that are themselves free of bacteria.

In reviewing a few of the causes given as external or exciting, we find in the first place that there must be a vulnerable cuticle upon which the irritant can act, and that this susceptibility may be either inherited or acquired. Though there is no apparent peculiarity in the minute structure of the skin, there is no question but that some persons have an idiosyncrasy, a susceptibility, of the cuticle to develop different forms of inflammation according to the nature of the irritant.

The want of cleanliness is frequently referred to as an exciting cause, but this *alone* will not cause any form of inflammation upon a normal skin. While an Acting Assistant Surgeon U. S. A. for a number of years I had occasion to come in contact with a number of Indians (the filthiest race with which I am acquainted), and I never saw a case of eczema among them. In hospital practice in New York City, Chicago, Ill., Louisville, Ky., and in this city, I have had occasion to treat many negroes and have found they are not as prone to the disease as the white race.

Though soap will remove the dirt, it makes the cuticle more sensitive by thinning the outerlayer and depriving it of its natural oiliness. I would not be misunderstood as advocating uncleanliness, but simply to emphasize the fact that the *overuse* of soap and water are harmful. We are all familiar with the patients who can submit to any kind of treatment except being deprived of their daily bath, even those who must have two full-length baths every day. Fortunately we know that the majority of these people are simply posing before the physician to show that they are more cleanly than "common folks," and then, too, it is so very English. (I actually saw an Englishman side-track his private car on the Northern Pacific Railroad, delaying his journey many hours so he could "take his tub".) Water, as a rule, is poisonous to an eczematous skin, and should be avoided as much as possible while the cuticle is acutely inflamed. Van Harlingen declares that "The insensate declamation against personal uncleanliness as an almost universal cause of skin diseases, which is too common, not only among superficial writers, but among physicians who ought to know better, would in many cases be better replaced by a caution against excessive ablution." After having waded through the maze of conflicting opinions in regard to the etiology of eczema, having consulted twenty-seven books and twenty-four monographs and extracts from medical journals, fifty-one authors in all, who are supposed to be thoroughly conversant with the subject upon which they have written, I freely confess I am completely confused in regard to the causes of eczema, as the disease is now classified. I can only conclude by stating my individual opinion in regard to the proper definition of the disease. As it is *now* understood it is a more or less chronic catarrhal inflammation of the skin, accompanied by peculiar symptoms that are caused by some form of irritation (external or internal) acting upon a susceptible cuticle. There must be primarily a certain condition of the skin itself—a predisposition, a susceptibility, a

vulnerability to take on the disease, either inherited or acquired. The latter state may be brought about by any constitutional disease that will produce systemic debility. I have already stated that I am not in accord with the prevalent view that there is such a thing as an *exclusively* "eczematous skin," but simply that the cuticle may be particularily susceptible to different forms of inflammation, varying according to the strength and nature of the irritant and the age, sex, nationality, and other factors pertaining to the patient.

So much for eczema as it is *now* classified; but I wish to place myself on record as predicting that some time in the near future the name eczema will be confined to that form of cutaneous disease that is caused by some specific parasite (Unna's morococci or some other bacteria) acting upon a vulnerable skin. I will now give a clinical account of a few cases of the disease, observed in my private practice, that may be of some interest from the fact that I have been unable to trace any definite causation; that the etiological factors are usually well pronounced, or from some other peculiarity not usually found in this disease.

As an example of an unusually severe case, and probable inherited predisposition I would mention that of Mr. C., seventy-five years of age. The body was affected from head to feet, and when I first saw the patient he said he had seriously debated whether it would be best to end his existence or submit to treatment. The pruritus was so severe that in his agony he would tear the skin with his fingernails, which he had allowed to grow long for this purpose, even resorting to the use of a stiff brush. He would walk the floor most of the night, procuring occasional naps in a chair. Most of the skin was of a vivid red, even of a violaceous color in patches, deeply infiltrated, objectively feeling like the cuticle of a "hide bound" horse. The skin about the inner portion of the thighs and legs was weeping profusely. This particular eruption first made its appearance on the face and had been diagnosed as erysipelas. He told me that the disease first made its appearance when he was about fifty years of age, and that a number of attacks had manifested themselves at intervals since that time; that otherwise his health was excellent in every respect, unusually so for a man of his age—neither gout, rheumatism, nor any other disorder had confined him to his bed for a number of years. During this attack no form of treatment had given him the slightest relief. He had been deprived of his usual occupation, that of lecturing on different subjects at several universities, confined to a darkened room, suffering intense agony physically and mentally, and with no hope for the future, even that death would relieve him. He was indeed to be pitied. I was fortunately enabled to give him some relief, till a few months later he died of pneumonia. Two years after his death his widow brought their twelve-year-old daughter to me, saying her husband had instructed her to immediately consult me if she or the child should again develop the disease. The patient complained of lassitude and pain in the back and abdomen. Her menses had just appeared for the first time. The eczema primarily appeared in the form of "milk crust" at one year of age. After being relieved it again appeared at about five or six years of age. This outbreak soon disappeared and she had no other manifestation of the rash till she consulted me. The eruption was of a vesicular type, situated in the face and ears. It soon disappeared under treatment and there has been no return in the last four years. This is the only case I can recall in which the tendency to the disease appeared to be distinctly transmitted to the offspring, the father having the disease when she was born, and she developing it a year after birth.

The following case is unique in my experience, and a good example of so-called "reflex eczema": Mr. C., nineteen years of age, suffered from vesicular eczema of the scrotum, penis, and inner portion of the thighs. Under local treatment alone there would be great improvement, but it was noticed there would be occasional acute exacerbations without any assignable cause. After being questioned closely, he confessed he had masturbated since he had been a young boy, that he had often tried to stop the habit, and had partially succeeded, but that recently the itching about the affected cuticle had been so severe he had to rub and stratch the parts vigorously to obtain relief. This so excited his passions that he would relieve himself by masturbating, and he continued to do this again and again during the night. In the morning he would feel, as he expressed it, completely "played out." The skin was intensely inflamed, edematous, and much infiltrated. After refraining from these gymnastic exercises he was cured within two months. It is now six years since he has had the slightest manifestation of the eruption. Though masturbation did not produce the disease, there is no doubt it greatly aggravated it after it had been once established.

Another case of reflex eczema is that of an infant, presenting papular eczema of the face, arms, and toes. The patient had good general health, but the disease did not respond to local treatment and regulation of the diet. I advised circumcision, as the prepuce was very long and I thought it might have something to do with the trouble in the way of reflex action. After the operation the child began to improve and was soon entirely relieved.

A report of several cases of typical neurotic eczema may be of some interest: Mrs. M., a young married woman, had good general health until she visited a high elevation in the mountainous region of Montana, when she began to suffer from severe headaches, irregular menstruation, and frequent fainting spells. A few months later she had occasion to travel several hundred miles by stage. One dark, rainy night, the stage driver being drunk, he nearly upset the conveyance over the edge of a precipice. She became frightened, hysterical, and jumped to the ground. Later she was found lying insensible in the deep mud, and drenched to the skin. On being placed in the stage she partially regained consciousness, only to faint again. She was conveyed to a tavern and put to bed, but on account of a severe diarrhea she had to be placed in a sitting posture. Several times on each occasion she complained of feeling faint, but did not become unconscious. In the morning a profuse erythematous eczema was observed upon the face, chest, and arms, accompanied with severe pruritus. In twenty-four hours the whole of the affected skin took on a vesicular condition, the face was much swollen, and the eyelids were nearly closed. Never before or since that attack has she had an eruption of any kind.

In a few cases of seborrheal eczema there was no assignable cause, either externally or internally. Miss T., aged thirty-two years, a professional nurse, suffered from seborrheal eczema in patches about the legs, thighs, arms, and scalp. Her health was good in all respects, though under great nervous strain on account of attending to her professional

duties, often being kept awake the whole night for weeks attending a patient with delirium tremens. The eruption, during this time, has gradually improved, till at the present there is no sign of the trouble remaining.

Mr. R., aged fifty-six years. Profuse seborrheal eczema, situated in arms, chest, legs, and thighs. The itching at times was very severe. The rash in the chest and arms appeared in patches of redness covered with the thick, greasy scales typical of this form of the disease. In a few weeks this portion of the eruption entirely disappeared, but the papular condition on the legs remained for a number of months, kept up from scratching the parts, the irritation being due to a number of varicose veins. In this case, too, I was unable to trace the eruption to any particular cause, the patient's general health being good in all particulars, except for occasional attacks of slight muscular rheumatism, but he had suffered in this way for twenty-five years without manifesting eczema. He indulged in the use of stimulants occasionally to excess, but this could hardly be counted as an etiological factor, as he continued to indulge his appetite in this way during treatment, and was cured by means of local treatment alone.

Mr. L., thirty-two years of age, presented very much the same form of rash as the last patient, situated in the same localities, and soon relieved by local applications. A month ago he again made his appearance, saying he had occupied a room with a friend, who, according to his physician, was suffering with scabies, and Mr. L. supposed he had caught the same disease. His eruption was a typical example of seborrheal eczema. He had never been ill in any way, and before the eruption appeared five weeks ago he said he had never felt better. He is now entirely well. I could, of course, report many such cases, but simply desired to call attention to the fact that it is absolutely impossible to discover any appreciable cause in many of these cases of eczema, and that they are perfectly amenable to treatment by means of local applications without any internal treatment whatever.

In my private practice I find that children under the age of six affected with eczema, are particularly robust, strong, and healthy. The only cause for the disease I have been able to find in the majority of these cases is improper food, not only in their being allowed too much candy—a small quantity is not harmful, as it simply satisfies a natural craving common to all children—but they are frequently given beer, tea, and coffee. (In one of my cases, a German parent allowed his five-year-old son a half-pint of beer a day), and allowed to come to meals with their parents and "taste" about everything on the table. I have frequently been able to relieve these cases by simply regulating the diet and applying locally some indifferent application. In public practice I have usually found the patients weak, anemic, so-called "strumous" children. Why there should be this difference I an unable to say. That the disease is of a more acute inflammatory type in children than in adults may be accounted for from the fact that in early life the skin is thinner and the glandular structure is more active.

A FEW SUGGESTIONS IN REFERENCE TO CONSUMPTION.

By L. BARKAN, M.D.,
NEW YORK.

Undoubtedly the great increase of fraternity, philanthropic institutions, and the understanding for public welfare and public utilities is to be traced back to the increase of knowledge and science. This promotion of science in general includes the promotion of economics, of hygiene, and the practice thereof, and these will be followed by a reduction of consumption, the scourge of the human race, which feeds on prejudices, brutal selfishness, and ignorance. There is an eternal law permeating human society that whosoever does not care for the common interest of his fellow men will be buried himself under the jaggernaut of his selfishness. The true welfare of the single individual cannot be separated from that of his fellow men. People have not yet been, however, sufficiently educated to this axiom, and while science has entered and permeated all branches of professional, industrial and agricultural life and the trades, it has not been taken up satisfactorily in our foreign and home political actions. The assertion of Gustavus Adolphus to his son: "You do not know with how much stupidity the world is governed," still obtains, and an outcome of stupidity in politics will probably be an epidemic caused by the continuance of the civil war in Russia and threatening the whole world. This shows the solidarity and reciprocity between different countries, and that not only the market price of goods of one country influences that of another country, but that political institutions and health conditions of one country react favorably or unfavorably on those of another.

Numberless are also the mistakes and the sins committed everywhere, as *e.g.* the overcrowding of the houses and the population in larger cities, the misplacement of towns and cities or sections thereof, and the wrong establishment of waterworks and especially the sewerage, which in certain cases it is impossible to improve or complete. I want to mention only a few striking instances. A big resort hotel in Florida was built on quite unhealthy ground. The California capital in San José, a healthful and lovely city, was removed by politicians to Sacramento, an unhealthful and malarial place. San Francisco, endowed by nature with splendid slopes and apparently destined to have the best sewerage in the world, has the poorest. There are so many bad and "dead" corners there that it will take years to improve the system, and a thorough cure will be impossible. Physicians have not been and are not consulted in such important matters of public health.

Herbert Spencer considers consumption to be a barrier to over-population, but there is no reason for this anxiety, at least not for a long time to come, if ever. If any artificial restriction and selection of the population must take place, teachings and legal measures should debar sick and delicate persons from matrimonial life and propagation of children. This is practised among Mohammedans, and especially in Turkestan.

The German poet, Schiller, said: "The stomach and love govern the world," but in our times of bad stomach and indigestion he would only recognize the rule of love. If sick and delicate people, whether poor or rich, were to be kept away and prevented from loving members of the opposite sex such a procedure would bring forth a favorable health influence on every matrimonial candidate. Presumably nobody would then do overwork or over-worrying, and the labor market would provide many more people with work and sufficient food than at present. On the other hand, we cannot but recognize the civilizatory and hygienic value of proper and limited work, and our endeavor should be to distribute such work more uniformly and systematically, to discover new channels for work, to bring capital and labor into the closest and quickest touch,

to substitute work for alimony, to cure patients, and to impart them such health conditions as to enable them to carry out their human task, to perform unextensive work. New industrial branches are always springing up, and there is yet plenty of tillable land in the world to give work, food, air, and sunshine to millions of people.

Our public and domestic hygiene is still defective, and there is plenty of room for reform.

Ceteris paribus, a patient traveling to his health resort should prefer a sea trip to a railroad trip, as the latter, by the dust creeping in everywhere, increases the danger of exacerbation. When Felix Niemeyer advised against sending away tuberculous patients he was decidedly mistaken. Thousands of cured people in Florida—who have reached old age—prove that it is not only of importance where the patient goes, but how and how far he travels.

The cheapest and most practical receptacle for the secretion from the mouth is a common matchbox, lined with soft or any other paper, and which at the first opportunity may be thrown into a fire.

To the disposal of the secretion of the nose, however, is not given due attention by any means. The court regulations and masters of ceremonies in the Middle Ages forbade the use of the hand for this purpose, and especially so at the table, while they inculcated the application of a handkerchief. What was a great improvement, then, is antiquated at present, and urgently requires a change to the better. We object to spitting bronchial secretion into a handkerchief, but hygienically there is no difference between the bronchial and nasal secretion, and both ought to be made harmless. The handkerchief, however, is quite a dangerous bacteria carrier and preserver chiefly on account of being stored in the depth of a pocket where a mild temperature, humidity, and seclusion of air and light contribute to the increase and spread of bacteria.

Wiping the nose in society, and especially at the table, ought to be discarded as being unesthetic. There is no logic in removing the nasal secretion publicly and other secretions privately. The nasal discharge may not only spread pneumonia and tuberculosis, but also their frequent precursor, influenza; and, furthermore, cerebrospinal meningitis and other purulent diseases. In case of influenza the handkerchief cannot house the quantities of secretion. The moistened handkerchief wets the fingers and the pockets, and influenza bacteria are deposited broadcast.

As a substitute for the handkerchief is to be suggested paper, either Chinese or preferably newspaper, which, by using the left hand near the nose and the right one above the head, forms a kind of stiff curtain, catching up all nasal secretion. The author has been using this method for years, but only once or twice per day, as he thinks that a too frequent removal of the nasal secretion done in a powerful way produces a mechanical irritation of the mucous membrane of the nose, and is apt to cause bleeding. At other times, when alone, he introduces cotton or, preferably, tissue paper or tar tissue paper tampons, which not only absorb and abduct the nasal discharge and germs, but desiccate the nose, and by producing a pressure on the nasal membrane reduce or check the reproduction of discharge probably in a similar way as pressure or a vaginal tampon will stop bleeding. Such tampons clogging up the nose may also be made use of with advantage in epistaxis. I have used them for many years, and have never experienced their escape into the pharynx.

At this occasion the remark might not be amiss that an operator with nasal catarrh should either have his nose tamponed or preferably not operate at all; the latter, of course, holds good for bronchial catarrh, too.

Another reform could be the establishment of roof hospitals or sanatoria in use for one or a few patients. The wind should not strike the patient, nor should it be reflected to a strong degree; the bed or the entire cottage should for this purpose be revolving. The wall of the head end, in order to catch up and divide better the wind or breeze, should be semicircular or semielliptic; the other walls should be high, and, like the roof, removable. The entire roof and walls, or parts thereof, could consist of twisted pine—or eucalyptus branches. In short, the cottage should have such a shape and condition that the wind should not exert its strength, would pass above and at the side of the patient, though providing him with plenty of fresh air. Moreover, a wall, when existing on the same or a neighboring house, ought to add essentially to the protection of the cottage and the patient.

One should not be afraid of "roof bacteria" spreading a disease, as fluctuating air does not deposit, but carries them far away and lands them where they seldom can do harm. This was at least my experience in the open-air treatment during the Russian-Turkish wars of 1876 and 1878, and this experience is corroborated by the scarcity of winds moving at an angle to the globe, by the different direction of winds on the top of masts and the deck, and by African dust found and analyzed in Berlin.

Convalescent consumptives have derived great advantage from performing my system of bed calisthenics while still confined to bed. The convalescent while doing exercise in bed is better off than when doing it outside the bed, as he can enjoy open windows and fresh air and still be protected by warm bed covers; later on he can also perform self-massage in bed. This work will take about half an hour a day, and in order not to get tired he ought to extend it over half or a whole day.

It is evident that this treatment will also be beneficial in other diseases, as in nervous cases, in rheumatism, gout, diabetes, and in surgical and other diseases where the circulation and respiration have to be stirred up without interfering, however, with a diseased organ in need of rest. The great importance of bed or horizontal gymnastics is shown in a beginning hernia or after a successful herniotomy, when, however, there is still a tendency to relapse. In both cases the upright position of the body and the downward pressure of the intestines will not permit gymnastics, but let the person exercise in horizontal position with a raised pelvis and the consequence will be an avoidance of the downward pressure of the intestine and a strengthening of the muscles and ligaments.

The question is often raised: When shall we have a reliable remedy for consumption like quinine in malaria? I take the opportunity to call attention to the very good effect of permanganate of potassium in tuberculosis, about which I published reports in the MEDICAL RECORD of 1895 and 1896; since then I have treated some more cases with this drug and have had the satisfaction of curing this dreaded disease in 31 cases out of 37. Half of the uncured patients had relapses by their own negligence.

Permanganate of potassium, the permanent antidote of corps poison, is also an excellent antiseptic remedy which, as well as sulphur preparations, I would like to try in meningitis cerebrospinalis.

454 WEST TWENTY-FOURTH STREET.

Tonsorial Asepsis.—For shaving a customer with a razor that had not been disinfected a barber at Eisenach, Germany, has been sent to prison for a month.

MEDICAL RECORD.

A Weekly Journal of Medicine and Surgery.

New York, February 24, 1906.

SYPHILIS IN MONKEYS.

AN experimental study of considerable importance and certainly of more than usual interest is that begun by A. Neisser nearly a year ago relative to the behavior of monkeys when inoculated with the virus of syphilis. It was in last March that Professor Neisser, accompanied by his assistants, Drs. Baermann and Halberstädter, went from Breslau to Batavia in order to prosecute their investigations on simian syphilis under more advantageous circumstances than had been possible in Europe, where monkeys of all sorts, and especially the anthropoid apes, are expensive, difficult to obtain, and hard to keep alive. Neisser returned to Europe some time ago and has now published a report on what has been accomplished in the *Deutsche medizinische Wochenschrift,* January 4, 11, and 18, 1906. His two colleagues are to remain in Java for an indefinite period longer in order to continue the observations, so that Neisser's communication is really only in the nature of a preliminary report. Some idea of the scale on which the work was carried out may be gained from the statement that there were kept constantly under observation ten to twenty orang-utans, twenty to thirty gibbons, and 600 to 800 smaller animals, while the total number of monkeys used in the experiments amounted to about 900. The observer's expectations in regard to the ease of obtaining and maintaining the animals were, however, not altogether realized, and Neisser says that although he had expected that even in the tropics there would be some difficulty in keeping the higher apes alive for any length of time, he was painfully astonished to find that intestinal diseases—dysentery and intestinal parasites—produced an enormous mortality among his stock. As regards the actual results obtained it must be admitted that but little that is going to have an immediate practical bearing on the treatment or prophylaxis of the disease has been ascertained. The entire subject is one that is comparatively new, however, and there is no doubt that the wholesale sacrifice of the Bandar-log carried out under the direction of the German scientist and his associates will result in laying a groundwork of observations that will prove a valuable starting point for further workers.

The report includes the discussion of a very large number of detached observations which do not as yet render any sweeping generalizations possible. The following few points are selected from the mass of material presented by Neisser. Although in general it was found that the virus of human and ape syphilis was more easily inoculable than that of the lower monkeys, this difference was neither pronounced nor constant, but it did seem certain that the more florid the process from which the material was obtained the more prompt and sure was the appearance of characteristic lesions at the site of inoculation. Successful results were obtained from primary glands, secondary lesions such as condylomata and mucous patches, and in some cases from tertiary products. Human blood and serum gave negative results, as did also experiments with simian organs such as spinal cord, liver, lung, kidney, muscle, and adrenals, while positive results were obtained from the spleen, bone marrow, glands, and testicle. Attempts to reduce the virulence of the poison by passage through lower monkeys were not conclusive, though Neisser apparently inclines to the belief that an increase of potency in this way is rather more likely. Out of forty cases in which syphilis virus and vaccine virus were inoculated together only twice did syphilitic infection take place. Attempts to produce infection by subcutaneous injection failed in every case. It was not found possible to devise any method by means of which the virus could be preserved more than a few hours, and it was found that eighteen hours after the death of an animal its virus had become inactive. Excision of the site of inoculation eight hours after the infection did not prevent the development of the disease, and the injection of mercury from the time of inoculation was also ineffectual in aborting the infection. In regard to the all-important question of immunity the results were not very encouraging. Indeed Neisser goes so far as to suggest that possibly what we are accustomed to call immunity in an individual who in consequence of a previous infection has become refractory to subsequent infections may not be immunity at all, and may depend simply on the persistence of a latent syphilis. Owing to lack of time the observers were not able to study the spirochete question very thoroughly, though Neisser favors the view that these organisms do stand in causal relationship to the disease.

While these few selections from the extensive report do not lead very far they indicate the importance of such investigations, and demonstrate the inadvisability of abandoning researches in this direction even though as yet they have not placed any new weapons in the hands of the therapeutist. We wish the expatriated scientists who are continuing the difficult work under what, no doubt, are very trying circumstances, success in their endeavors, and trust that in their next report they may be able to present something that will be of practical as well as of academic importance.

CLINICAL RESEARCHES ON THE VISCOSITY OF THE BLOOD.

THE change in the viscosity of the blood in health and disease has never been satisfactorily investigated, for the lack of a suitable method for estimating the changes which are believed to occur. Hitherto such examinations have been limited to specimens of blood which were either defibrinated or treated with certain oxalates to prevent clotting, and these procedures, although necessary, produced changes which were found to invalidate the final results to a greater or lesser degree. The improve-

ments in technique which have lately been developed in this branch of research work have, however, greatly stimulated the interest in the subject. Among the noteworthy contributions which have lately appeared is one by J. Bence (*Zeitschrift für klinische Medizin,* Vol. 58, No. 3), who has studied the phenomenon in a number of diseases, particularly in those of the circulatory and respiratory apparatus. Bence also extended his investigations to the more practical aspect of the question and studied the effects of various therapeutic agents which were believed to influence this property of the blood; we say believed, for, aside from the effect of venesection and the action of the iodides, we know very little of the latter subject.

It has usually been assumed that the viscosity of the blood remained unchanged and did not require to be considered in estimating circulatory conditions. Bence shows, however, that this assumption is not correct and that certain changes which occur, particularly in cardiac disease, are very well marked. As the result of his observations in a large number of cases, he finds that the viscosity of the blood rises and falls with the quantity of carbonic acid which it contains. This condition is brought about by alterations in the volume and the contour of the red blood cells, produced by the agency of CO_2, which may also be demonstrated in the circulating blood itself. By reason of this increased viscosity, blood overloaded with carbonic acid naturally exerts its effect on the heart. If the overloading is the result of cardiac insufficiency, the latter defect will be further increased. In suitable cases, inhalations of oxygen will reduce the viscosity of blood which contains abnormal quantities of carbonic acid by favoring the elimination of the latter, and in this manner the cardiac insufficiency may likewise be relieved. In nephritis the blood is apparently less viscous than normally, and the explanation of this phenomenon must be sought for in the hydremia which is usually present.

As regards the effect of various articles of food on the viscosity of the blood, Bence was unable to determine by animal experiments with the methods thus far developed any facts which would warrant a satisfactory conclusion, so that as far as any practical advance is concerned, but little has been added to our knowledge. The work constitutes, however, another example of the refinement to which laboratory methods have been extended in an attempt to solve some of the problems connected with modern medicine.

THE ENTRANCE OF AIR INTO THE CIRCULATION.

It is a matter of common belief that the entrance of air into the circulatory system is extremely dangerous, and may rapidly lead to a fatal issue. Most text-books on surgery and physiology have supported this view in their pages, the symptoms are carefully described, and a warning note is usually sounded with regard to the possible direful consequences of this accident. The fatal issue is attributed to the fact that the air finds its way into the right side of the heart, from which it cannot be expelled by the ventricular contractions, and interferes with the circulation to such an extent as to cause acute anemia of the brain, syncope, and death. These views have become so well established that any expressions to the contrary are almost revolutionary in their boldness, although the results of a number of investigations cast great doubt on their truth.

Among the latest investigations in this subject are those made by E. A. Larned (*Surgery, Gynecology, and Obstetrics,* December, 1905), who claims as the result of his animal experiments that air embolism is not necessarily fatal, or even attended with grave results. Some of his most conclusive observations were made in horses. In a number of these, increasing volumes of air, varying from twenty to two thousand cubic centimeters, were deliberately introduced in the veins. The most prominent symptom consisted of labored respiration, the degree of the disturbance depending on the quantity of air injected, but death itself could be brought about only by the continuous introduction of air under pressure, and in this instance it amounted to several liters. Several smaller animals were also experimented upon with similar results, and in only one case, in which twenty cubic centimeters of air were suddenly injected into a rabbit weighing two pounds, did death ensue. This quantity of air would roughly correspond to 450 c.c. in a child weighing forty pounds.

A noteworthy feature in all these experiments was the train of symptoms similar to those associated with dyspnea. The air evidently entered the heart and stopped the circulation, or it passed on into the branches of the pulmonary artery, shutting off the blood supply from some particular part of the lung, in this way producing dyspnea. If sufficient air is injected, the pulmonary circulation may be interfered with to such an extent as to cause death, but the entrance of a number of bubbles can do no more than temporarily close a few small branches and then the absorption of the air by the blood takes place.

These experiments fully confirm the careful observations already made by Senn, Hare, and a number of other investigators in smaller animals, and show quite conclusively that the danger to life from air embolus is largely overestimated. The effects are in direct proportion to the volume of air introduced into the venous circulation, and the large amounts which are referred to in these experiments are not likely to enter into the question in operative work. Less alarm need therefore be felt when, during the course of an operation in the vicinity of a vein, the peculiar hissing sound is heard which has been taken to indicate the entrance of air into the vessel, nor probably need any reproach be felt if a small bubble is accidentally injected with the hypodermic needle into the tissues. It seems to have been sufficiently well demonstrated that the belief that harm can result from such an accident is not well founded.

The Action of Glycerin on Bacteria.

Glycerin has come to be quite universally adopted as a vehicle for the preservation and administration of vaccine virus and similar material. It has been found not only to conserve the activity of the virus for a longer time than any other preservative agent thus far tested, but also to exert a marked influence on its bacterial content. It has been suggested, how-

ever, that other factors might also be concerned in the destruction of the bacteria present in glycerinated virus. With the idea of throwing some additional light on this question, a thorough study of this subject has been made by J. J. Kinyoun (*Journal of Experimental Medicine,* Vol. VII, No. 6), and as a result of this work a number of facts have been accumulated which add not a little to our knowledge of the matter. A closer scrutiny into the effects of glycerin on the bacteria present in vaccines showed that its employment had not been attended by uniform results, both temperature and specific variations in the bacteria exerting a well-marked influence. It was also determined that the bacteria, as a general rule, were destroyed much more rapidly in vaccine emulsions containing glycerin alone than in cultures to which glycerin was added. In another series of experiments it was shown that certain bacteria in pure culture were destroyed more slowly by glycerin than in vaccine or tissue emulsions. Kinyoun was thus led to believe that the tissue fluids or the cell contents might in some way be concerned in producing this sudden reduction in number, and also that this reaction might occur through some combination between the glycerin and the constituents of the emulsion, or by virtue of the glycerin extracting from the cells some peculiarly active bactericidal substance. Other observations also confirmed the fact that glycerin alone will destroy certain pathogenic bacteria only with difficulty, and that while blood serum can effect this same end, the process is in its nature a very slow one. When normal blood serum and glycerin are mixed together, however, they bring about the reduction of the bacteria much more quickly than either fluid alone. Another peculiar fact noted was that immune sera are less effective in this respect than normal sera, or at least in the latter the reduction proceeds with greater celerity. In order to obtain the most striking results with mixtures of serum and glycerin, the latter should be mixed with the serum before being added to the material containing the bacteria. The gradual extension and application of methods of vaccination renders this paper of timely import and interest.

The Tenement House Law.

There are few measures passed in recent years by the Legislature of this State which have been productive of greater good to the community than the Tenement House Law. Designed, as it is, for the protection of the tenants, it is naturally not favored by the owners, who object to anything that reduces the income derived from the rental of their buildings, and it is therefore not surprising that efforts are made every year to nullify the law. This year two amendments have been proposed, both of which are bad. One of these is a proposition to give to the Tenement House Commissioner discretionary power to remit fines for violation of the law; the other would change the definition of a tenement house from a building occupied by more than two families to one occupied by more than three families. The first of these amendments is palpably vicious and would afford such an opportunity for graft to a dishonest commissioner that it is inconceivable that it could be entertained by the Legislature. The second is apparently more innocent, but when it is considered that over 20,000 houses in New York city with more than 300,000 tenants, are occupied by only three families, and that these would then be deprived of sanitary supervision, it is seen to be almost equally bad. The Tenement House Law is an excellent law as it stands, and any attempt to tinker with it in the Legislature should be stoutly resisted.

News of the Week.

Army Medical Corps Examinations.—Preliminary examinations for the appointment of Assistant Surgeons in the Army will be held on May 1 and July 31, 1906, at points to be hereafter designated. Permission to appear for examination can be obtained upon application to the Surgeon General, United States Army, Washington, D. C., from whom full information concerning the examination can be procured. The examinations will be held concurrently throughout the country at points where boards can be convened. In order to perfect all necessary arrangements for the examinations of May 1, applications must be complete and in possession of the Surgeon General on or before April 1. Early attention is therefore enjoined upon all intended applicants. There are at present twenty-five vacancies in the Medical Corps of the Army.

Special Hospital for Dying Consumptives.—The President of the Cook County (Ill.) Board, Mr. Edward J. Brundage, has urged the Commissioners to consider the erection of a special building in the grounds of the County Hospital for dying consumptives. The number of tuberculous cases has increased in Chicago to such an extent that the corridors of the hospital at Dunning, Ill., are filled with patients. Hopeless cases and patients in a dying condition are thrown together and the majority of cases in the later stages prove fatal on account of the rough journey from Chicago to Dunning. President Brundage says that the inhumanity of sending dying patients to Dunning must be apparent. Patients are frequently carried by ambulance over miles of rough road to the hospital there, only to die within a few hours after their arrival. The horror of this procedure demands a prompt remedy. Provision must be made at the County Hospital for the dying consumptives, and such accommodations when established must be reserved exclusively for advanced cases, and the hospital at Dunning continue to be the institution for the treatment of hopeful tuberculous patients. The Building Committee of the County Board has voted to build an emergency hospital for consumptives adjoining the County Hospital.

An Institution to Combat Infantile Mortality.—In an effort to reduce Germany's infantile mortality, which is said to be surpassed only by that of Austria and Russia, an institution is to be founded in Charlottenburg, a suburb of Berlin, under the patronage of the Empress, who has contributed a considerable sum for the purpose. The object of the institution will be largely educational, and departments will be provided in which nursing women with their infants will be received for three months at a time. Others are intended for pregnant women, for labor cases, for artificially nourished children and for children born outside of the institution. A hospital section for sick children, a model dairy, a training school for midwives and nurses, and chemical and bacteriological laboratories will also be included. The records show that of 2,000,000 children born in Germany in 1903, 405,000 died during their first year.

Opposition to a Staten Island Tuberculosis Sanatorium.—If a bill introduced at Albany on February 14 becomes a law the project of establishing an institution for the care of consumptives on Staten Island will have to be abandoned. The bill is intended to accomplish this through an amendment to the New York city charter giving local boards of improvement the power to recommend the establishment of penal institutions and hospitals within their districts, and making further provision that no such insitu-

tion or hospital shall be established in any borough if such local board, by vote of three-fourths of its members, disapprove.

Hospital Policemen.—In order to avoid the unnecessary expense of detailing separate policemen to watch prisoners under treatment in hospitals a special squad, known as the hospital squad, has been created in Brooklyn. This consists of twelve men, six of whom will be assigned to the Brooklyn Hospital and six to the Eastern District Hospital, to which institution all disabled prisoners will be removed. It was found that last month 417 policemen had been detailed to watch prisoners at the hospitals at an estimated cost to the city of $3,389.

Building Operations at State Hospitals.—On February 14 the State Lunacy Commission awarded contracts for work to be done upon State hospitals at Rochester, Poughkeepsie, and Willard. At Rochester the north building of the hospital group is to be remodeled. At the Hudson River State Hospital refrigerating apparatus is to be installed, and at Willard a contract was let for the construction of a new cold storage building.

New Hospital for Oak Park (Ill.)—The new hospital of the Sisters of Misericordia, of Montreal, will be erected in Oak Park this spring. A plot, 170 by 307 feet, in the southern end of Oak Park has been purchased, and on it will be constructed a five-story building. The purchase price was $10,000, and was paid by Dr. J. W. Tope. The building will cost $100,000. The construction will be of brick and stone, and the hospital will contain sixty beds.

Annex to Presbyterian Hospital.—The Presbyterian Hospital of Chicago, is to have an annex, a pavilion, which will cost approximately $400,000. The erection of a strictly modern hospital is assured by E. A. Hamill's announcement that $352,000 already has been contributed to the building fund. Part of the money will pay for repairs and improvements on the old building, but the new structure will be erected exclusively for the accommodation of pay patients.

New Medical Society.—A society to be known as the Eastern Illinois Ophthalmological and Otological Society was organized January 16, at Champaign, Ill. The permanent officers will be elected and the organization perfected at a meeting to be held in Decatur, March 6.

Harvey Society Lectures.—The tenth lecture in the Harvey Society course will be delivered by Professor Charles S. Minot of the Harvard Medical School at the New York Academy of Medicine on Saturday, February 24, at 8:30 P. M. Subject: On the Nature and Cause of Old Age.

The Middleton Goldsmith Lecture of the New York Pathological Society was delivered at the New York Academy of Medicine on February 23 by Dr. Ludvig Hektoen, Professor of Pathology in the University of Chicago. The subject was "Phagocytosis."

Warren Triennial Prize.—Dr. Herbert B. Howard, Resident Physician of the Massachusetts General Hospital announces that competition for this prize will be on some special subject in Physiology, Surgery, or Pathology. Dissertations must be legibly written, and must be suitably bound, so as to be easily handled. The name of the writer must be enclosed in a sealed envelope, on which must be written a motto corresponding with one on the accompanying dissertation. Any clew which reveals the name of the writer before the award of the prize, will disqualify him from receiving the same. In case no dissertation is considered sufficiently meritorious, no award will be made. Dissertations will be received until April 14, 1907. A high value will be placed on original work. The Warren Triennial Prize was founded by the late Dr. J. Mason Warren in memory of his father. The judges are the physicians and surgeons of the Massachusetts General Hospital. The amount of this prize for the year 1907 will be $500.

Congress of the German Roentgen Society.—The second congress of this society will be held in Berlin on April 1 and 2, just preceding the thirty-fifth congress of the German Surgical Society which takes place April 4 to 7. Inquiries, as well as announcements regarding papers to be read before the Roentgen Society should be directed to the President, Professor Eberlein, Berlin N. W. 6, Luisenstrasse 56; or to the Secretary, Dr. Max Immelmann, Berlin, W. 35, Lützowstrasse 72.

Research in Serum Pathology.—The Department of Pathology and Bacteriology of Indiana University, Bloomington, Ind., announces that the position of research assistant in serum pathology in Indiana University for 1906-1907 is open for applicants. Candidates must have completed at least two years' work in a medical school of high grade, and must have a fair knowledge of bacteriology, of general pathology, and of volumetric and gravimetric methods of quantitative chemistry. Preference will be given a medical graduate.

The Fifth Congress of the German Orthopedic Society will be held in Berlin on Tuesday, April 3, 1906, on the day preceding the opening of the thirty-fifth congress of the German Surgical Society. Announcements regarding papers to be read are to be sent to Professor Joachimstahl, Berlin, W., Magdeburger Strasse 36.

New York State Homeopathic Society.—At the annual meeting of the Society held in Albany on February 14 the following were elected as officers: *President,* Dr. Newton W. Collins, Rochester; *First Vice-President,* Dr. T. Drysdall Buchanan, New York; *Second Vice-President,* Dr. Frederick W. Seward, Jr., Goshen; *Third Vice-President,* Dr. O. S. Ritch, Brooklyn; *Secretary,* Dr. H. Worthington Paige, Oneonta; *Treasurer,* Dr. F. M. Dearborn, New York; *Necrologist,* Dr. John L. Moffatt, Brooklyn.

To Stop Smoking by Children in England.—It is expected that there will be little opposition to the passage of a bill to be introduced at this session of Parliament, which is intended to suppress cigarette smoking by children. The draft of a measure has been prepared which prohibits the sale of cigarettes to children under 16, and makes any child under 16 found smoking any kind of tobacco liable to conviction and punishment. Sir William Broadbent is one of the supporters of the measure.

Gifts to Charitable Institutions.—Five charitable institutions in Brooklyn have each received $10,000 from Peter Wyckoff. The institutions are the Eastern District Hospital, the Eastern District Y. M. C. A., the Homeopathic Dispensary and Hospital, the Industrial Home, and the Graham Home for the Aged.

Bad Food Given to Steerage Passengers.—The captain of a transatlantic steamer was arrested on February 15, charged with providing unwholesome food for infants in the steerage. Several other captains of ships in the immigrant transportation trade have also been arrested for failing to obey the statutes relating to the accommodation of steerage passengers.

Stony Wold Sanatorium.—An appeal for funds has been made by the Stony Wold Sanatorium to enable it to accept a conditional gift of $13,500. The amount needed is $1,926.50, to complete a total of $18,500, which the donor of the conditional gift requires shall be raised before his contribution shall be available.

Health Conditions on the Isthmus.—According to a dispatch received at Washington on February 16, health conditions in the canal zone are excellent. During January there were 22,000 employees on the rolls. The average daily number of sick was 503, or 22 per 1,000. Seventy-four deaths occurred among the employees, including 26 from pneumonia, principally among negroes. There was then no quarantinable disease on the Isthmus. The last case of yellow fever at Colon was reported December 11; the last case at Panama, November 11.

Fifteenth International Medical Congress.—At a recent session of the German national committee having charge of the arrangements for the medical congress at Lisbon it was agreed to submit the following two recommendations for adoption at the time of the congress. One suggestion is for the organization of a permanent international bureau, having its headquarters in Paris and authorized to deal with any questions relating to the arrangements for congresses, the selection of speakers and topics for discussion, etc., and the other is to the effect that the international congresses be held only once every five years in future instead of every three years.

An Appropriation for Prof. Neisser.—A number of members of the Reichstag, representing different parties, have united in endeavoring to secure for Prof. Neisser an appropriation of 100,000 marks to enable him to prosecute his researches on the nature of syphilis.

Seasickness.—The Parisian Ligue Contre le Mal de Mer has chartered a steamship which will start from Hamburg and call at Antwerp, Dover, and Cherbourg on its way to Lisbon, which will be reached in time for the beginning of the International Medical Congress. Several hundred medical men have already signified their willingness to travel on the ship and test on their own persons the efficacy of the many remedies that have been suggested for seasickness.

The "Annals of Gynecology and Pediatry."—Dr. E. W. Cushing, after eighteen years of editorial service, has resigned the management of this monthly to Dr. John Van Doren Young, under whose direction the January number has appeared.

Orange Hospital's Name Changed.—The Hospital of the Immaculate Conception at Orange will hereafter be known as St. Mary's Hospital.

Antivivisection at Length.—According to the newspapers a petition measuring seven miles in length and signed by 630,054 persons, is to be presented to the British Parliament next session asking that a bill be passed for the prohibition of the vivisection of dogs.

International Laryngo-Rhinological Congress.—The Viennese Laryngological Society is organizing an international congress of laryngologists and rhinologists to be held in Vienna April 21 to April 25, 1908. The occasion is to commemorate the establishment of laryngology on its present basis by Turck and Czermak fifty years ago, as well as the semi-centennial of the society. The President of the society is Professor O. Chiari, and the Secretary Professor M. Grossmann, IX., Garnisongasse 10, Vienna.

International Food Exhibit.—An international pure food exhibition will be held at Antwerp during April and May of this year. Medical and pharmaceutical exhibits, and particularly those relating to sanitation and hygiene, will form important features. Details may be obtained from the office of the secretary, 26 Rue d'Arenberg, Antwerp, Belgium.

Fox River (Wis.) Medical Society.—At the annual meeting of this society, held at Green Bay, the following officers were elected: *President*, Dr. R. E. Minahan of Green Bay; *Vice-President*, Dr. W. R. Hicks of Menominee, Mich.; *Secretary and Treasurer*, Dr. H. W. Abraham of Appleton.

Officers of the Chicago Laryngological and Otological Society.—At the annual meeting, recently held, Dr. Otto T. Freer was elected *President*, and Dr. Geo. E. Shambaugh, *Secretary*.

New Hospitals to be Erected.—A new hospital to cost $200,000, is to be built by the Chicago Lying-in Hospital and Dispensary. Plans are being made for a nurses' dormitory for the Mary Thompson Hospital for Women and Children, to accommodate thirty-one nurses, and to cost about $20,000. Plans have been prepared for the Cribside Pavilion, to be erected in connection with the Chicago Memorial Hospital, to cost about $40,000.

Obituary Notes.—Dr. Warren Elliott Harrigan of Williamsburg, N. Y., died on February 14, as the result of an attack of heart failure which came on while he was prescribing for a patient. He was forty-two years old and a graduate of New York University.

Dr. Florence De Hartt of Jersey City, died suddenly on February 12, in Trenton, where she was resident physician of the State Home for Girls. She had practised in Connecticut prior to becoming associated with her sister, Dr. Clara De Hart, in Jersey City.

Dr. William V. McKenzie of Metuchen, N. J., died February 14, after a long illness. He had practised in Metuchen for more than seventeen years and was president of the local Board of Education, member of the Board of Health, and president of the Middlesex County Medical Society.

Dr. William L. Shoemaker of Georgetown, D. C., died on February 8, after an illness of over a year, at the age of eighty-three years. Dr. Shoemaker was a graduate of Jefferson College and of the University of Pennsylvania Medical School.

Dr. A. H. Butts of Charleston, W. Va., is dead of pneumonia at the age of seventy-two years. Dr. Butts was born in Louisburg, W. Va., and had practised medicine since 1860, when he was graduated from the Richmond Medical College of Richmond, Va. At the outbreak of the Civil War he enlisted in the Confederate Army and served as surgeon until the cessation of hostilities.

Dr. Benjamin Franklin Grant of Bath, N. Y., died on February 17, at the age of seventy-nine years. He was a member of the United States Board of Pension Examiners for Steuben County. Dr. Grant was graduated from the Homeopathic Hospital College, Cleveland, O., in 1867.

Dr. J. G. Robison of Rogers, Ark., and well known in the northwestern portion of the State, died on January 25, of pneumonia, at the age of forty-six years. He went to Rogers from Kansas City, Kansas.

Dr. C. A. Duval of Houma, La., died on January 23, after an illness of seven weeks. Dr. Duval was born at Gallatin, Tenn., in 1832, and served as a Confederate surgeon during the Civil War, until the surrender at Vicksburg. He was repeatedly elected coroner and health officer of his parish, and was serving in these capacities at the time of his death.

GENERAL PARALYSIS OF THE INSANE A BACILLARY DISEASE—EVOLUTION OF GYNECOLOGY—UNCONTROLLABLE VOMITING IN PREGNANCY — BOSSI'S DILATOR — CHOLECYSTITIS — HEXAMETHYLENAMIN IN DIAGNOSIS—PHAGOCYTOSIS OF RED CORPUSCLES—EXCESSIVE ZEAL OF SANATORIUMS.

LONDON, February 2, 1906.

THE Morrison lectures at the Edinburgh College of Surgeons were this year intrusted to Dr. W. Ford Robertson, who gave the final lecture on Monday. He has taken the occasion of making an announcement of the greatest interest. As the result of researches carried on at the Royal Edinburgh Asylum, as well as the Scottish Asylum, he regards general paralysis of the insane as a bacillary disease. This is no hasty conclusion, but is offered as the result of investigations extending over five or six years in the institutions above named, and in which Dr. M'Rae participated. Others have conjectured that the disease originated in a bacterial invasion, and work has been done with a view of determining the question.

Dr. Robertson has found the microbe, which he describes as a diphtheroid bacillus, in the blood, in the cerebrospinal fluid, and in the walls of the cerebral arteries. In nine out of twenty-three cases of general paralysis he had made cultures from the bacillus obtained. There was some resistance to staining. It may be confidently expected that Dr. Robertson's conclusions will be speedily confirmed or corrected by other observers; meantime I may summarize his view. He holds that the disease is dependent on the invasion of the tissues by the bacillus, which morphologically closely resembles that of diphtheria. He contends that the previous infection of which the paralysis has been assumed to be a late result is only a predisposing cause which prepares the soil for the reception of the microbe. The organism gains access to the tissues through the mucous membrane. It can always be found in the alimentary canal. Probably sound membranes can prevent its entrance, but inflammation or other injury to the membrane would open the way for the invasion of the bacilli.

There are other predisposing causes, the chief among them being chronic alcoholism, and perhaps excessive indulgence in nitrogenous food. There is some hope that an antiserum might be of use, and Dr. Robertson said he should certainly try it, although in other bacterial diseases the method so far had seemed to him to have been rather disappointing.

Dr. Lloyd Roberts delivered on the 19th inst. his valedictory address to the North of England Obstetrical and Gynecological Society, in which he said that in the early days of gynecology the operator aimed directly at the object to be gained, estimating the dangers and difficulties roughly. Early methods therefore were crude, devoid of niceties of execution. Then improvements were made until simplicity was overlaid with complexity. Next attention was fixed on details, to the surmounting of isolated obstacles, often at the expense of the unities of the operation. Finally reaction set in, complicated methods were abandoned, and a return made to primitive simplicity, but shorn of its crudeness. Crude directness of purpose gave place to elaboration, and that in its turn to effective simplicity, marking the high-water mark of applied knowledge. This thought was illustrated by reference to operations for cancer, vesicovaginal fistulæ, etc. The same thought was applied to the operator who, Dr. Roberts said, had been evolved from the obstetric physician and he from the man-midwife; and there is a tendency to give up his original work of attending labors. But there must still be the skilled obstetrician. To him investigations into prenatal pathology offered a rich field for study.

At the Medical Society's last meeting Dr. Comyns Berkeley read a paper on "Uncontrollable Vomiting in Pregnancy," in which he distinguished that due to the gestation from that only associated with it. In the vomiting due to the pregnant condition he said many cases were neurotic and could be arrested by suggestion. But severe pernicious cases were toxemic. It had been suggested that this symptom, eclampsia, and acute yellow atrophy were all caused by the same toxin. Vomiting associated with pregnancy might be due to displacement (reflex cases), or to some definite disease in other organs, *e. g.* intestinal obstruction. Hyperemesis gravidarum is intimated to be fatal in 50 per cent. of cases treated, but Dr. Berkeley thought if a post mortem were made in every case the percentage would be shown to be less, as some other cause of death would be found in a number of fatalities. He thought premature labor should be induced earlier than was the practice; it was too often done when too late, and the mother died. Moreover, if done earlier it would, when the cause was not pregnancy, lead to a discovery of the concealed disease by the persistence of the vomiting afterwards.

Dr. G. Blacker then read a paper on "Dilatation of the Cervix Uteri by Bossi's Dilator." This, now in use for some fifteen years, he said, enabled the operator in practically all cases to effect dilatation according to the urgency of the case. The method was successful even in primiparæ, in whom the cervix had undergone no shortening or dilatation, and there was no extra risk of septic infection. The average time required when the canal was intact was twenty-four minutes; when partially obliterated, eighteen minutes; it is thus the most rapid method short of incisions. Patients usually pass through a normal puerperium. Dr. Blacker admitted the grave risk of tearing the tissues, and that even in the most favorable conditions lacerations might occur. Therefore the dilator should only be used in the most urgent cases, *i. e.* when grave danger to the life of the mother or child is present and rapid emptying of the uterus is likely to lessen that danger. Indiscriminate use of the instrument might seriously injure the cervix, or even the lower uterine segment.

Two cases of cholecystitis treated with inoculations of *Bacillus coli* were communicated to the Pathological Society on the 16th inst. by Professor A. E. Wright and Staff Surgeon Reid. Both were operated on for calculi, but pyrexia, jaundice, and other symptoms subsequently induced the authors to try inoculations of the bacilli raised from those found in the mucus discharged. The immediate result was to make the patient worse, but the mucus diminished, bile began to pass into the intestines, and complete recovery ensued.

At the same meeting Mr. Dudgeon read a preliminary communication on the use of hexamethylenamin for distinguishing between the *Bacillus typhosus* and *Bacillus coli*. He had obtained constant results. The *Bacillus typhosus* grew well in 0.1 per cent. hexamethylenamin broth, fairly well in 0.5 per cent., though delayed, but in 1.0 per cent. the broth was always sterile. The *Bacillus coli* gave abundant growth in 0.1 per cent., and also in 0.5 per cent., and a fair growth even in 1 per cent. If a tube of 1 per cent. broth were inoculated with *Bacillus typhosus* and incubated at 37° C. for twenty-four hours, then diluted two or three times and reincubated no growth resulted. Some further experiments with paratyphoid bacilli were related and Mr. Dudgeon is continuing his investigations.

Professor Wright read a note on "Phagocytosis of Red Corpuscles," which he had observed incidently in a case of cellulitis and another of cystitis. Both were pneumococcal infections. On examining the blood in these cases it was found that several red corpuscles were within white cells. In a third case the same thing was observed. Dr. Wright remarked that in these cases anemia and cachexia were marked, and he thought that the vitality of some of the red corpuscles was lowered by the toxin in the serum, and that consequently the injured ones were taken up by the leucocytes. Dr. C. J. Martin said he had met with the same thing in examining fibers from the spleen of animals which had died of plague.

Excess of zeal on the part of sanitary officials is leading to opposition to their authority. From various parts of the country strong protests are heard from time to time about their arbitrary proceedings. The same thing occurs in some London districts, and I have heard fierce denunciations of "sanitary tyranny." It seems a pity that useful measures should thus be exposed to the danger of falling into ill-repute. Here is a sample of excessive zeal brought to my notice. A case of scarlet fever was notified, the doctor further certifying that there was no occasion for removal. The sanitary inspector differed and got a magistrate's order, armed with which he terrified the mother into consent, and the child was taken to the hospital and kept at the expense of the ratepayers, although the parents were able and willing to pay their own doctor and nurse. You may think the medical officer of health would support the attending doctor. Not at all. He was rather concerned to exonerate his staff, and suggested that the nurse had thought the surroundings unsuitable. Another parallel case was met in the same way by the same medical officer of health. He is not a bad fellow, though he has rather a high opinion of himself, and I should like to warn him that if he continues thus to connive at unwarranted actions he may be called upon to defend his action in court, in which event he can scarcely expect sympathy from neighboring practitioners who have been treated in this way. There is no doubt that in one case the removal was illegal, and if the parents had prosecuted the connivance of the medical officer of health would have exposed him to an unpleasant experience.

The steady increase of insanity, says the *Hospital*, during the last fifty years is one of the most alarming of all adverse conditions of the public health.

OUR PARIS LETTER.

(From Our Special Correspondent.)

APPOINTMENT OF DR. ROBIN—MEDICOLEGAL ASPECTS OF RADIOTHERAPY—INDEX OF REFRACTION OF BLOOD SERUM—SCHOOL BOOKS AND CONTAGIOUS DISEASES—HYDRONEPHROSIS—CALCIUM CHLORIDE AS A HEMOSTATIC—DEATH FOLLOWING MERCURIAL INJECTIONS — INFANTILE MONGOLISM — TRACHEAL CELLULITIS—HYGIENE OF THE SKIN AND SCALP.

PARIS, February 1, 1906.

THE chair of clinical therapeutics of the Faculté de Médecine of Paris, supported by the generosity of the Duc de Loubat, has been provided with an incumbent in the person of Dr. Albert Robin. At the Académie de Médecine Dr. Chauffard presented a very interesting report on the medicolegal aspects of the therapeutic use of the Roentgen rays. The author first referred to the marvelous discovery now ten years old made by Professor Roentgen of Würtzburg, and traced the development of its application to medicine. First came radiography, then direct examination on the fluorescent screen, or radioscopy, and finally the adaptation of the various facts discovered to the science of radiotherapy. After having recalled the important observations of Sabouraud, who showed that ringworm could be cured by the localized use of Roentgen rays, the author described the application of the rays to the treatment of tumors. Side by side with these conquests the author reviewed the frequently serious injuries that may be produced by radiotherapy, among which are destruction of the leucocytes, atrophy of the ovarian follicles or of the testicle, and consequently azoospermia in man and sterility in woman. Chauffard concluded that the therapeutic use of the rays should be exclusively restricted to physicians. Radiology should form as indisputable a branch of medical science as any other of its departments. The interests of the public even more than those of the physician demand that the application of radiotherapy shall be reserved exclusively to members of the profession. The conclusions suggested by the commission and presented by Dr. Chauffard having been put to a vote were unanimously adopted by the Academy.

Tuffier and Mauté communicated a report on the study of the index of refraction of the blood serum in surgical affections. Their observations were made by means of the Zeiss immersion refractometer, which has the advantage of requiring only a single drop of serum. In the normal state and at the temperature of 17.5° the index of refraction of human serum varies from 1.3491 to 1.35205. The authors' researches conducted on over 200 cases have led them to conclude as follows: The index of refraction of the blood serum decreases after considerable hemorrhages, the fall being proportional to the amount of blood abstracted. Fasting lowers the index of refraction but little during the first twenty-four hours, but if the abstinence from food is protracted it may reduce the figure considerably. In cases of extensive burns this method permits the estimation of the variations of the fluid portion of the blood. In double renal disease the index of refraction is ordinarily lowered, although the results are not always consistent. Excepting in various forms of nephritis and extensive loss of blood the index of refraction has but little relation to the nature of the disease, but its systematic observation in operative cases has shown that it has considerable prognostic value. On this account alone the method should be further investigated, especially as it is simple, rapid, and gives accurate results.

Lop of Marseilles read an interesting paper concerning the transmission of infectious diseases by school books. He paid particular attention to the prophylactic measures necessary to prevent the dissemination of contagious diseases in this way, especially in schools. He pointed out the necessity for disinfecting all the books in common use at the end of each school year, while every book belonging to a pupil who contracted a contagious disease should be disinfected at once. In the author's experience the most satisfactory method of disinfection was found to be that of Micquel, in which formaldehyde is used.

At its first session in December the Société de Chirurgie elected Professor Mauclaire as honorary member. The following officers were elected for 1906: *President*, Dr. Segond; *Vice-President*, Dr. Quénu; *Secretaries*, Dr. Michaux and Dr. Chaput; *Treasurer*, Dr. Arrou; *Registrar*, Dr. Broca.

Dr. Pierre Delbet presented a specimen of hydronephrosis due to kinking of the ureter over an abnormal artery. The specimen very clearly showed the angulation of the ureter over the ectopic vessel. While there was no doubt in regard to the rôle played by this abnormal vessel in causing the hydronephrosis it seems that this structure acquired its etiological significance only through a prolapse of the kidney.

Toubert read an interesting communication on the use of calcium chloride as a prophylactic against hemorrhage. On account of its harmlessness, its efficiency, and simplicity of application the author considered that calcium chloride was an excellent hemostatic, being rather preventive than curative. Toubert gives his patients on one or two evenings before the operation a solution containing three grams of calcium chloride, which is to be taken in small doses two or three times during the day, the last dose preceding the operation by only a few hours. By this means the author believed that the coagulability of the blood was distinctly increased in all his patients, and he never encountered secondary hemorrhage or hematoma even after operations which predisposed to those conditions. Calcium chloride therefore seems destined to serve not only the physician and the specialist, but also the surgeon, in both major and minor surgery.

At the Société Médicale des Hôpitaux Le Noir reported two cases of death in the course of antisyphilitic treatment by subcutaneous injections of gray oil. An interesting discussion followed this paper. Brocq was of the opinion that, in spite of these unhappy results, injections of gray oil should not be discarded, for he believed that this was the best routine method for treating syphilis in workingmen and those whose occupations were confining. The method was efficient, sure, and without pain. It was necessary, however, to take certain precautions before applying it, and never to use it on persons whose teeth were in poor condition or on those having defective kidneys. Thibierge also considered that injections of gray oil were the best method of treatment for syphilis, but he never made use of them in treating patients with poor teeth or having albuminous urine. Legendre said that he had observed accidents indiscriminately after all mercurial injections, most often in using calomel, but also after injections of gray oil, of biniodide, and of cyanide. The complications were observed in cases in which there had been no preliminary analysis of the urine.

Comby demonstrated an interesting case of infantile Mongolism. The patient was a boy of two and a half years who, although of white race, suffered from Mongolian idiocy. His round face, brachycephalous head, and his narrow and slanting eyes gave him the appearance of a Chinese baby. His skin was yellow, dry, and flaccid, the limbs flabby and the penis rudimentary. Although the child was very backward and could not talk, it was able to recognize its parents; it was restless and fretful, and could be quieted only by music. The child presented all the characteristics of Mongolism, a variety of congenital idiocy first segregated by Langdon Down. All idiots of this class presented the same type of Asiatic facies, which was noticeable from birth. The author believed that this anomaly was frequent, and said that in two years he had observed it twelve times. The children were always feeble and predisposed to tuberculosis. It had often been noticed that such children were the latest comers in a numerous family, and maternal old age and exhaustion had been cited as an etiological factor. In the author's cases most of the mothers had been young, but all had suffered great sorrow during their pregnancy. Dupré emphasized the importance of maternal emotion in the etiology of the affection, especially when the period of stress occurred during the later months of pregnancy. Ballet observed that in certain cases myxedema was associated with the symptoms of Mongolian idiocy.

At the Société de Pédiatrie Broca and Dufour reported a case of tracheal cellulitis observed in a nursling that had been intubated in the latter stages of croup. The description of this case gave rise to a lively discussion on the advantages of intubation compared with those of tracheotomy. The conclusions were that although intubation had marked advantages, the method was not to be recommended, for it predisposed to complications, and besides it was impossible to diagnose juxtalaryngeal abscesses before making a tracheotomy incision.

Jacquet delivered an interesting discourse on the hygiene of the skin and hair before the Société de l'Internat. He pointed out the important rôle played by the nervous system in the pathology of the skin and scalp. He explained that falling of the hair, especially, was occasioned by a productive impulse of new hair growth through the functional stimulation of the epithelial follicles. The loss of hair taking place in severe fevers was also due to cutaneous stimulation and formed part of the general functional stimulation which was often manifested under these conditions by unexpected growth of the individual. The rôle of nervous stimulation was well demonstrated in the occurrence of baldness, which was a disease of the intellectual. He indicated that baldness had become more common among women since they had been devoting themselves to a greater degree to mental work. Jacquet insisted that in dermatology the principal etiological rôle was not played by microbes and their toxins, but by an excess of functional stimulation. The hygiene of the skin would therefore involve the hygiene of the body as a whole, especially alimentary hygiene, and the hygiene of the scalp would be hygiene of the brain.

OUR LETTER FROM THE PHILIPPINES.

(From Our Regular Correspondent.)

A MEDICAL SCHOOL IN MANILA—DISCUSSION ON TROPICAL ULCER—THE CHOLERA SITUATION—PERSONAL.

MANILA, P. I., December 30, 1905.

THE first step toward providing a medical education for Filipinos, based upon American ideas, was taken by the Commission when it passed Act 1415, November 25, 1905. The Act is entitled: "An Act Establishing a Medical School and Defining the Manner in Which It Shall Be Controlled and Conducted."

Section one provides that there shall be established in Manila a medical school, to be known as the Philippines Medical School. It is to be organized under the laws governing corporations.

Section two provides that the powers of the corporation shall be vested in a body to be known as the Board of Control for the Philippine Medical School. It shall consist of the Secretary of Public Instruction, the Secretary of the Interior, one member of the Philippine Commission, and one who shall be designated by the Governor-General. The Dean of the faculty shall also be an ex-officio member of the Board of Control.

Section three provides that the Board of Control shall have the power to receive endowments and bequests, and to provide for their disposition; to nominate to the Governor-General for appointment, the faculty of the school, and to fix the duties and responsibilities of its members; to confer the degree of Doctor of Medicine upon such persons as are recommended by the faculty; to make to the Commission recommendations in regard to the condition of the school, and to present estimates for appropriations necessary for its maintenance.

Section four provides that upon the request of the Board of Control, heads of departments and officers of the Insular Government are authorized to furnish apparatus and supplies as they may be required, and to detail employees for duty in the medical school, and employees so designated shall perform these services and the time so employed shall count as part of their prescribed service to the Government.

Some preliminary work has been done with a view to starting the medical school at the beginning of the next school year. The Director of Education has now about twenty Filipino students undergoing a preparatory course in medicine, and it is hoped that they will be able to pass the necessary entrance examinations for the Medical School.

There is porobably no feature with regard to the sanitary condition of the Islands that is fraught with more importance than the supplying of adequately and properly trained Filipino medical men to take positions in the provinces. At the present time there is a woful lack of properly trained physicians for that work.

At the regular December meeting of the Manila Medical Society no formal papers were read, and instead a discussion took place on tropical ulcers, in which Dr. Cook spoke upon their etiology, Dr. McDill, their clinical aspect, and Dr. Woolley, their pathology. No particularly new points were brought out in the discussion.

The cholera situation in Manila still continues to be favorable, and an average of only about one case per week is reported. The disease in the provinces is not spreading very far from Manila, still, it continues to shift its base, and an average of 15 to 20 cases per day are reported.

Dr. J. D. Long, Passed Assistant Surgeon, U.S.P.H. & M.H. Service, who has been on duty in the Quarantine Service, during the past three years, in Manila, has been appointed Assistant Director of Health, in the Bureau of Health, and will assume his duties January 1, 1906.

Assistant Surgeon Snyder, U.S.A., who has been acting as Quarantine officer at the port of Jolo, has been detailed for duty in Manila, and his place will be taken by Major Ewing, U.S.A.

FOOD PRESERVATIVES.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR:—In your esteemed publication of January 27 you have an interesting article on the Pure Food question. This question is certainly a serious one. There is no doubt about much of our food being adulterated with cheap, inferior, and sometimes dangerous adulterants. To regulate such conditions a national pure food law is certainly essential. However, in our immense country we have to ship edibles from the Atlantic to the Pacific, and from the Gulf to the Great Lakes; consequently some method of preserving perishable articles of food must be resorted to. We could dispense with adulterated and artificially colored foods, as adulterating food certainly lessens its food value and coloring matter does not enhance the food value, so why should not both be abolished?

When a substance is used to preserve an article of food it can hardly be deemed an adulterant, as it is not used to lessen the food value, but to maintain the full strength and to keep the article preserved in a comparatively fresh condition. When we use the ordinary methods of preserving food, however, such as salt, sugar, smoke, vinegar, alcohol, etc., we do not keep the food in a fresh condition, and such substances have a tendency to destroy the natural flavor of the article preserved. We could not preserve all of our meats, fish, fowl, and oysters, with the ordinary methods, neither could we preserve them satisfactorily with cold storage, as it has been proven time and time again that cold storage does not entirely prevent the process of decay. Many cases of ptomain poisoning have been traced to articles of food that have been kept in cold storage too long. The practice of shipping fowl, fish, crustaceans, etc., containing their entrails should be prohibited, as articles in such a condition have decomposed matter stored in them that make conditions favorable for the propagation of toxic germs. There is no greater menace to the health of a nation than tainted, partially decomposed articles of food. Conditions favorable for the growth of germs could be overcome by using some method to keep food comparatively fresh and healthful. So if we want to protect the nation from poisonous germs, we cannot do so by enacting laws prohibiting the use of preservatives.

In studying the food question thoroughly and investigating the various kinds of preservatives used, I have already learned that borax and boric acid are used more extensively on fresh meat and fish than any other substances. And I have learned that while they are condemned by Dr. Wiley, Chemist of the Bureau of Agriculture, they are pronounced innocuous by Prof. Chittenden of Yale. Prof. Chittenden made exhaustive experiments to determine the effect of borax and boric acid on the digestive organs, and concludes his report by saying that when borax and boric acid are used to preserve food they have a tendency to accelerate the flow of gastric juices, thereby aiding instead of retarding digestion. England has laws permitting the use of borax and boric acid. She demands that her meats be packed in borax and her butter preserved with boric acid. In looking up statistics, I find we shipped to England during the fiscal year of 1903 and 1904, hams, 169,703,849 pounds; bacon, 196,822,713 lbs., a total of 366,526,562 lbs., all of which were preserved with borax; and during the fiscal year of 1904 and 1905 England imported 407,794,000 pounds of butter, all of which was preserved with boric acid. To preserve the hams it required 6,750,000 pounds of borax; to preserve the butter it required 2,038,970 pounds of boric acid, making a total of 8,788,970 pounds of borax and boric acid practically consumed in England annually. England has been consuming foods preserved with these substances for years, and she has found by practical experience that these preservatives are beneficial to health instead of detrimental. I can see, therefore, no reason why they should be condemned as poisonous preservatives in this country.

H. H. LANGDON.

TICK FEVER.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR:—In the MEDICAL RECORD of January 20 I find mention of "spotted fever," "tick fever," or "mountain typhus." In all cases I have treated during the months of February, March, April, and May (I have not seen it during other months) in the past three years there has been distinct evidence of tick infection. In all cases there has been an inflamed area of about two inches diameter, and some sloughing. In some I found the heads of the ticks. I have had about twelve typical cases.

LOUIS HOWE, M.D.

CODY, WYOMING.

Progress of Medical Science.

Boston Medical and Surgical Journal, February 15, 1906.

Serious Head Injuries and the Indications for Operative Treatment.—The salient points in the conclusions presented by B. Sachs are as follows: (1) If there is extensive skull injury, particularly in the parietotemporal region, evidence of the splintering of the inner table, of foreign body or persistent intracranial hemorrhage, one should operate immediately. (2) In comminuted fracture the surgeon must decide whether or not the danger of infection will be increased by surgical procedure. (3) These questions must all be decided on purely neurological lines. (4) The great point to decide is whether the brain has or has not been tangibly injured, and, if so, whether the injury is accessible or not. Symptoms of increasing intracranial pressure may call for trephining if lumbar puncture or other simpler methods do not afford relief. (5) Conservatism is advisable even in accessible injuries. Hemorrhages are often

absorbed and inflammatory processes often recede. (6) In determining the gravity of brain injury, disturbances of cardiac and respiratory action, of vesical and rectal control, and the condition of consciousness are the most important symptoms. They are the manifestations of increasing intracranial pressure, and of other serious injury. Recovery from coma, however slight, after twenty-four, forty-eight, or seventy-two hours, is encouraging; deepening coma is of grave significance. The behavior of the pupillary reflexes is of no special value in deciding the question of operative interference. (7) If the symptoms point to distinct focal lesion, although years may have elapsed since the initial injury, surgical measures must be adopted, providing only that the lesion be accessible. (8) If the external injury points to one site and the symptoms to another, consider both; attack the site of external injury first, but try to reach the other as well.

Head Injuries.—Morton Privei would decide the question of operative intervention upon the following points of evidence: (1) The nature of the blow. A person may have a severe fall, and yet the head may not be severely injured, while, of course, the reverse may be the case. If a person falls from a height, striking his head, presumably the brain is lacerated; but a fist blow or a fall on the street might merely break an artery without bruising the brain; (2) general symptoms, as coma, stertor, pulse, temperature, etc.; (3) neurological indications; (4) surgical evidence of skull injury. Increasing experience leads the author to advise conservatism in operating.

Indications for Operation in Head Injuries.—Assuming the absence of contraindications such as heart or kidney lesions, etc., W. N. Bullard would advise operation in compound fracture of the outer surface of the cranium. It is safer in adults to operate also in simple fracture of the external surface. All depressed fractures should be operated on. We should operate in (1) all cases with symptoms of middle meningeal bleeding; (2) in adults in whom unconsciousness after injury lasts more than twelve hours, and when we can clearly assign the unconsciousness directly to the injury; (3) when persistent unilateral convulsions (referable directly to the injury) follow in an adult; (4) the question of operation arises in cerebral or meningeal paralysis immediate following a severe head injury. Hemiplegia or monoplegia under such conditions are not absolute contraindications. They may be referable to causes which have produced the fall on the head itself; (5) inequality of the pupils occurring immediately or shortly after injury is an indication in favor of operation; (6) temperature: Immediate and persistent rise of temperature (not otherwise accounted for) occurring after severe head injury suggests contusion or laceration of the brain. Rise of temperature within twenty-four to seventy-two hours after injury, especially if the patient is unconscious, suggests secondary encephalitis or inflammation of the brain; (7) pulse: Slow pulse suggests compression, hence, with other symptoms, is an indication for operation. Rapidity of the pulse in itself does not contraindicate operation. Weakness of the pulse may be a contraindication.

New York Medical Journal, February 10, 1906.

A Case of Cerebrospinal Meningitis Indicating that It May Be of a Contagious Nature.—H. A. Hare records the case of a man of 23 years who was taken suddenly ill with severe headaches and soon developed opisthotonos, violent rigidity of the cervical muscles, and loud cries. Large doses of diphtheria antitoxin and morphine had no effect, and he died of circulatory and respiratory failure forty-four hours after the initial seizure. Forty-eight hours later his attending physician (who had called Dr. Hare in consultation) came down with mild symptoms suggesting the same malady. He grew worse, however, and died eight hours after the development of distinct meningeal symptoms, and nineteen hours after his first symptoms appeared. The original patient had visited, four days before his illness commenced, a territory in another State in which the disease was then present. A medical student who helped to care for him developed a violent tonsillitis with severe constitutional symptoms. Dr. Hare also developed, four days after seeing his patient, chill, fever, and severe pain in the neck, back, and limbs. In his own case he used 4,000 antitoxin units as a prophylactic, knowing that it would probably do not harm, and might act as a preventive.

The Dietetic Treatment of Chronic Diarrhea.—Max Einhorn divides chronic diarrhea into the following forms: (1) Diarrhea due to chronic intestinal obstruction; (2) nervous diarrhea; and (3) chronic diarrhea, due to catarrh of the small intestine principally, sometimes also accompanied by a catarrhal condition of the colon. Most forms of chronic diarrhea principally involve the small intestine; and this group can again be subdivided into (1) primary catarrh; (2) catarrh depending upon abnormalities of gastric secretion; and (3) catarrh accompanying ulceration. In all the dietetic desideratum is the selection of foods which are non-irritating and leave little residue. They must not be cold when ingested. In (1) liquid food is essential (milk, raw eggs, broths, and meat juices). In (2) a generous diet may be allowed, except that all laxatives should be avoided. The patient must be encouraged in his efforts to suppress the constant desire to defecate. In (3) in achylia gastrica proteids should be excluded. A distinctly vegetable diet is called for. Gruels, milk, kumyss; later bread and butter are permissible. Later a little meat may be added. All the solids should be finely divided. If the diarrhea is due to hyperchlorhydria a richly albuminous diet is necessary. Alkalies should be given. It is not essential to give hydrochloric acid in achylia gastrica. In the cases due to trouble in the small intestine, we must exclude such substances as fruits, salads, highly-seasoned dishes, etc., which encourage peristalsis, but see that the patients take enough food. Egg albumin water may suffice for a few days. Then one may go on to eggs, decoctions of barley, oatmeal and rice porridges, bread, butter, and meats. Cold foods must be avoided. If the diarrhea persists tannic acid, or even an opiate, may be necessary.

Some Displeasing Results of the Mastoid Operation.—J. A. Stucky's deductions are based on an experience of 128 operations, fifteen of them being radical. Of the entire number 40 per cent. had nearly all the external evidences of pus. Five of these were of the Bezold variety, and the pus had burrowed down into the neck under the cleidomastoid muscle. In nine others the abscess had ruptured or been opened by the attending physician and sequestrum of the cortex had sloughed out of the wound, leaving the vitality of the soft parts so much impaired that much of it had to be removed, making healing by granulation a necessity. These cases resulted in ugly scars, some of them being remedied by plastic operations. Some atresia of the canal was the result in three cases, due to faulty packing and neglect of after-treatment. Facial paralysis due to neuritis in three cases, one following a second operation for osteomyelitis, one in which the vertical portion of the canal was destroyed by the disease leaving the nerve exposed, and one in which the nerve was injured by too forcible use of the curette during the operation. All of these patients completely recovered in from two to four months. In the fifteen radical or Stacke-Swartze operations the results have been all that could be desired, except that in five cases obstinate granulations and lowered vitality prolonged the after-treatment to a degree annoying and discouraging to both patients and physician. In all of these patients has the hearing been improved by the operations, and the author has had no fatalities. One of the most surprising after-results has been in the improvement in the general health of the patients, especially in the chronic cases. He has operated in only five acute cases, patients who have not had any previous pain or suppuration in the ear, the majority suffering from acute exacerbation upon chronic condition.

The Early Diagnosis of Gastric Cancer.—H. Weinstein comments on the different significations attached to the term "early" diagnosis. He considers it advisable to regard with suspicion all cases of patients above forty wherein with a history of previously healthy digestive organs, dyspeptic symptoms, and persistent loss of appetite, especially of animal food begin to be complained of. All such cases, when coupled with rapid loss of strength, require the most careful analysis, and the physician must not consider his duty performed until he has either proved or disproved the existence of malignant disease. In this connection the family history of the patient with regard to carcinoma must be carefully inquired into. A history of more or less recent traumatism in the region of the stomach must be taken into consideration, as a trauma may give an impetus to the development of a neoplasm in predisposed individuals. The motor and secretory functions of the stomach must be carefully examined. One should test for an absence of hydrochloric acid and the ferments which with the presence of lactic acid and the Oppler-Boas bacillus will speak for carcinoma. The presence of hydrochloric acid and absence of lactic acid fermentation, however, does not exclude malignancy, for in ulcus carcinomatosum we usually find hyperchlorhydria; the history of a preexisting ulcer will lead in the right direction. Occult hemorrhages occur in the stomach even in the early stages of the disease, and it is not unusual to find blood and pus on careful microscopical examination of the stomach contents. If, in addition to these signs, a blood examination shows an absence of digestive leucocytosis, a diminution of the red corpuscles, and a reduction in the proportion of hemoglobin, the diagnosis of cancer is almost certain.

American Medicine, February 10, 1906.

Puerperal Infection.—Ellice McDonald reviews the lesions of puerperal infection and directs attention to the three forms infection may take, toxemia, septicemia, or

pyemia. The frequency of the various infecting organisms is considered and the subject of sapremia reviewed. Six cases illustrative of the more unusual terminal forms of puerperal infection are reported. The cases are discussed separately and general conclusions are deduced that, while streptoccoccus is the most common infecting organism, other types of infection not infrequently cause severe symptoms. The term puerperal infection should be broadened to include infection elsewhere than in the uterus and the nature of location of such lesions should be recognized before any operative measures are undertaken. The harmfulness of curettement is dwelt upon.

Facts About Eating.—John Warren Achron says that where a sick headache (mixed migraine), biliousness, hyperacidity, duodenal ulcer, spastic constipation, chronic rheumatism, bronchitis, asthma, postnasal catarrh, eczema, acne, pruritus, neuralgia, insomnia, cerebral hemorrhage, arteriosclerosis, Riggs' disease, frequent urination, physical weariness (that tired feeling), obesity in some of its forms, and many other ailments and conditions are present there is or has been overeating of some sort, too much eating of one kind of food, meals are taken too near together, there is "nibbling" between meals, the food taken is not being properly insalivated, it is being washed down by liquids in excess taken with it, or after meals independently of the food ingested. The question is not so much one of individual foods as it is one of control in habits of eating, and of restriction of food to the actual physiological needs of the system. If diseases are to be cured or unorganized exudates absorbed, the restriction must be carried to the point where the system lives for a time and in part, at least, on the waste locked in its tissues and carried in the blood. This is simply a matter of "cleaning house," and the food, like the sail of a boat, must be trimmed flat enough to allow the body to weather the conditions present. Starches and sugars are the foods that common experience has shown are the most likely to clog the system. Meats or other foods require to be controlled, depending upon the indications.

Abscess of Antrum Causing Symptoms of Acute Articular Rheumatism.—H. K. Wheelock reports a case of pneumococcic infection of the antrum of Highmore, which developed polyarthritis with general symptoms of acute articular rheumatism. The patient had been suffering from a "cold in the head" with free discharge from the right nostril from the beginning of the attack. The frontal sinus was washed by means of a cannula, and on the following day she had a severe chill which was followed by a rise in temperature and she was confined to her bed for twenty-four hours. Later she had severe pain in right knee, left elbow, and shoulder. This pain and tenderness lasted about forty-eight hours. The second day following the chill, the temperature was 100° F. Pus from the first was to be seen between anterior end of middle turbinate and external wall of right naris. Exploratory probe puncture was made and two teaspoonfuls of thick pus worked out, which showed pneumococci. Following the flushing of the antrum the naris was free from pus. Pain returned on the following day, when the antrum was again flushed and about one teaspoonful of pus brought away. Patient made a rapid recovery following the last lavage and regained the weight which she had lost during her illness.

Cleansing of Milk Vesseis.—A. H. Stewart, in his efforts to obtain clean milk for Philadelphia, has made a thorough investigation of the prevailing methods for cleansing milk vessels. He found that many dealers entirely neglect this important procedure, while a majority of those who have a regard for cleanliness employ methods which fail to accomplish the desired result. He cites the best results obtained from an examination of milk vessels in a number of establishments and commends a method used by a small percentage of dealers. It consists of washing the bottles and cans by a powerful stream of some hot washing powder solution with rapid solvent power pumped into the bottles which are then rinsed with boiling water. This method cleanses 95 per cent. of the bottles perfectly. Tables showing the results obtained from an investigation into the comparative values of washing powders as regards the destruction of germs, rapidity and thoroughness of action, and expense entailed by their use are given. Sodium carbonate would seem best for cleansing purposes, for besides meeting all the requirements it has the advantage of being cheapest in price. Dr. Stewart asserts that the filling of dirty milk bottles on the streets by the men who deliver milk in wagons and the return of cans to the farm without any washing whatever are matters which should receive prompt attention. He makes a strong plea for the establishment, under supervision of the Bureau of Health, of can washing and cleansing buildings where all cans may be sterilized before they are sent to the farms. The advantages of such a scheme would be: (1) Saving of milk which is now destroyed by rapid fermentation due to infection from dirty cans. (2) Saving of ice used to preserve milk which is eventually lost. (3) Saving of time. (4) Abolition of the use of preservatives. (5) Saving of space for the storage of empty cans. (6) Increased sale of milk due to restored confidence in its purity. (7) Saving of the lives of thousands of children who are now fed on fermenting milk, the food value of which has been lost. (8) Prevention of epidemics of dysentery and other milk-borne diseases.

Journal of the American Medical Association, February 17, 1906.

Ulceromembranous Angina and Stomatitis.—This affection, usually occurring in young individuals and due to a peculiar fusiform bacillus, commonly associated with a spirillum, is described in detail by G. H. Weaver. The bacillus is an obligate anaërobe, appearing usually as a long, slender rod, thickened at the middle, and with pointed ends. It stains best with carbolfuchsin, but also with Loeffler's methylene blue and with anilin water solution of gentian violet. It does not stain by Gram's method. It is found most abundantly in the early acute stages of the disease and decreases as recovery advances. The spirillum or spirochete is slender and delicate, presenting usually three or four turns. It stains uniformly but less intensely than the bacillus, does not stain by Gram's method, and is usually actively motile. The association of the two organisms seems fairly constant. Weaver finds no support for the view that the two organisms are identical. The proof that they are the essential etiological factors of the disease, he says, is not complete; further study of pure cultures may be expected to give more light on the subject. There is rarely much, if any, fever. The lesion is sometimes only accidentally discovered, the symptoms are so insignificant. Usually the local condition is observed after from one to five days of premonitory signs, lassitude, throat discomfort, etc. Its chief symptoms are dysphagia, salivation, and fetid breath, but these are not constantly present. With the oral and tonsillar lesions there may be swollen glands, earache, and nasal discharge. Various complications, albuminuria, herpes, gastroenteritis, noma, were observed by Weaver, and many others have been reported by different observers. He thinks that the disease is very prevalent, but often overlooked because of its mildness. Contagion has been observed, but close contact seems to be required. The diagnosis is made by the finding of the organisms, but care must be taken to exclude diphtheria by proper culture methods, as the diphtheria germ may be associated with the fusiform bacillus. The prognosis is usually good, though in severe cases gangrenous processes and noma of the face may develop. According to Vincent and Richardier, the prognosis is bad in children. A tendency to recur has been observed. As regards treatment, some authorities speak highly of the use of potassium chlorate. Various antiseptic solutions have been used and tincture of iodine is spoken of with favor by some. Silver nitrate locally has been employed. Weaver thinks that peroxide of hydrogen applied directly to the seat of the disease is most useful because of the anaërobic nature of the bacillus. At the Memorial Institute for Infectious Diesases it was used successfully followed by a solution of carbolic acid and sulphocarbolate of zinc, 5ss and 5ii respectively, in a six-ounce mixture.

Surgical Treatment of Goiter.—R. W. Hardon advocates the surgical treatment of goiter and reports three cases in which partial thyroidectomy was performed for Graves' disease with good results. His conclusions are, in substance, as follows: 1. Every irregular tumor of the thyroid, no matter how small, should be removed, since in this way only can we save the lives of those having malignant growths. 2. Every regular tumor of the thyroid causing symptoms other than mere deformity, should be resected when after a few months' medical treatment the growth is not checked and no improvement is produced. 3. Avoidance of needless traumatism, care of the stump, free drainage, and salt solution to keep the blood and lymph vessels full and to prevent absorption from the wound are points especially mentioned in connection with the operation.

Mucocele of the Appendix.—A. Stengel reviews the literature of reported cases of cysts of the appendix and remarks on their probably different pathological characters. Some of them are undoubtedly mere inflammatory retention cysts, caused by the occlusion of the intestinal communication of the appendix. He has seen a number of such, all of moderate size and evidently of inflammatory origin. Exceptionally they may be of such size and may have lost the characters of inflammatory retention cysts to such an extent as to be classified as cysts and to cause doubt as to their mode of formation. Mucoid and possibly colloid carcinomatous cysts, however, are comparatively rare; he has met with but one instance—that which he reports—in about 2,000 autopsies. It occurred in a woman, aged fifty, who died of rapidly developing acidosis after prolonged

glycosuria. In this case, while the nature of the process is still somewhat uncertain, closer study led him, contrary to his first impression that it was simply a dilated appendix filled with mucoid material unusual in amount and character, to suspect, from the presence of irregular acini, epithelial tubular structures, and collections of epithelial cells scattered throughout the gelatinous substance that the condition might be allied to colloid cancer.

Acute Abdominal Symptoms in Typhoid Fever from Inflamed Mesenteric Glands.—R. S. Rowland reports two cases of typhoid fever illustrating the occasional difficulties of diagnosis. Both patients had pronounced abdominal symptoms; in one, perforation was suggested by the symptoms of pain, collapse, etc.; in the other, appendicitis and tuberculous peritonitis were both suspected as complicating a possible typhoid fever, the characteristic signs of which had not yet been fully developed. In both cases, operation revealed, not the conditions suspected, but inflamed mesenteric glands. Rowland finds little positively stated in the literature on this complication of typhoid fever. His conclusions are given as follows: 1. "In some of the cases in which exploration showed no cause for the symptoms, these were probably due to changes in the mesenteric glands. 2. Some of the recoveries which have been reported from intestinal perforation without operation probably occurred in cases of this sort in which the symptoms simulated perforation. 3. McCrae's suggestion that pain and acute abdominal symptoms might be due to enlarged mesenteric glands is credible, and further observation and study will probably show that this condition is not, relatively speaking, a rare complication in typhoid fever."

The Lancet, February 3, 1906.

Some Points in the Treatment of Heart Failure in Diphtheria.—C. Bolton lays stress on two points: (1) prevention of cardiac failure, and (2) rest, both mental and physical. The first embraces the earliest possible administration of antitoxin. It leads directly to the neutralization of the toxin. The latter becomes very speedily combined with the particular tissue affected by it and is then neutralized only with great difficulty by the antitoxin. In human diphtheria the toxin is not suddenly poured into the blood as in an experiment, but it is poured slowly, and it is therefore possible to neutralize it by large doses of antitoxin. It must be remembered that extensive fatty degeneration of the heart may occur in the short space of three days. Moreover, the remedy must be given in large doses. Most authorities agree that the initial dose should be from 4,000 to 6,000 units. The author goes so far as to say that in a severe case as high a quantity as from 12,000 to 24,000 units should be given at once, and if on the next day there is no improvement in the nasal discharge or separation of the membrane, or if the latter has extended, the injection should be repeated. He finds no greater liability to rashes, joint symptoms, etc., with large doses than with small ones. The matter of rest is all important. In the acute stage of the disease, when the heart is failing, sudden death may occur at any time as the result of the strain of vomiting or jumping up suddenly in bed. If the acute stage is survived and the patient left with signs of heart failure due to changes not in themselves sufficient to kill him, strain may again determine sudden death. On the other hand, if he have no signs whatever of heart failure, the strain of getting up too early in the progress of the disease often initiates it, thus bringing into evidence the latent heart weakness.

Eucalyptus Oil as a Vermifuge in Ankylostomiasis.—The virtues of this remedy are extolled by L. P. Phillips, who advocates the use of a saline purge in the evening to be followed early the next morning by one-half of the following mixture: Eucalyptus oil, 2.50 grams; chloroform, 3.50 grams; castor oil, 40 grams. In half an hour's time the second half of the mixture is taken. The patient is kept in bed, fasting, until the bowels act. Should any depression occur after the first dose, the second is omitted. In young boys and feeble, anemic patients the dose is divided into thirds and given at intervals of twenty minutes. It can be repeated, an alternate days. As a rule from three to four liquid stools follow. In 44 cases this plan was wholly successful. That the chloroform is essential is shown by the fact that in three cases in which the ova were present chloroform water was given by mistake (instead of the spirits) and the result was negative. In 26 additional cases the results were styled "efficient," while in 33 others the result was either unknown or negative, the treatment being employed in some for diagnosis or else a mixed treatment was adopted. Cardiac depression from the remedy as above described is rare.

Aberrant Vaccinia.—The case of M. E. Paul was that of a woman whose baby had been vaccinated with good effect two weeks before she came under observation. On her own chin, just below the border of the lip, was a large mature vaccine vesicle. The lip was swollen and very painful. Considerable constitutional reaction was present. The sore began its usual course without incident. The author regards the baby's finger-nail as the most probable instrument of inoculation.

Dermoid Tumor of the Mediastinum in a Child of Two Years.—The patient of G. Carpenter presented signs of compressed lung on both sides, and nearly a pint of straw-colored, opalescent fluid was withdrawn from the chest. The latter became quite resonant behind but remained absolutely dull in front. The front bulged considerably and occupied more of the right side than the left. The tapping was repeated with temporary benefit. The child was later brought to the hospital, cyanotic and moribund, and died shortly afterwards. Autopsy gave the following findings: Both pleuræ were healthy. In front of the right lung was a mass of the size of a fist. On incising this from six to eight ounces of clear fluid escaped; inside the cyst was some cheesy material with a few hairs lying at the bottom. The rest of the tumor felt hard. The right lung was much compressed. The mass removed was roughly spherical. In addition to displacing the heart slightly to the left it projected into the anterior mediastinum and reached to the inner surface of the left lung. The right lung was compressed into an airless strip which lay behind; the compressed lung did not occupy more than one-half of the space of the lung on the opposite side. On section the tumor was chiefly composed of a considerable number of cysts, the largest of which was the cyst which had been opened. Between the cysts running from above downwards was a partition composed of fat and fibrous tissue and containing a few calcareous masses. Most of the cysts contained a gelatinous material of a light brownish color. In the large cyst which had been previously opened were sebaceous-looking material and short hairs.

British Medical Journal, February 3, 1906.

At What Age Should a Cleft Palate Be Closed?—R. W. Murray prefers as a general rule to postpone operation until the child is between two and three years of age, and advocates complete closure at one operation. He reasons as follows: In order to obtain a well-formed and freely movable soft palate, excess of cicatricial tissue must be avoided. If the cleft of the soft palate is closed during infancy, this can only be done by means of a turnover flap, which of necessity leaves a raw surface to granulate, and will ultimately cause some contraction and stiffening of the parts. If, on the other hand, the operation upon the soft palate is postponed until the child is about two years of age, there is more tissue to work with, and it is generally possible to fashion a good soft palate and uvula by paring the edges of the cleft and uniting them in the middle line. Excess of cicatricial tissue is thus obviated, for union takes place by first intention. Though he has of recent years operated upon the hard palate during infancy and closed the cleft of the soft palate later, he is not convinced that the subsequent powers of articulation in these children have been better than in those in whom the complete operation has been postponed until the second or third year.

Preliminary Note on the Cytorrhyctes Luis (Siegel) and the Spirochæta Pallida.—A. MacLennan found that in two cases of primary syphilis the serum from the cleaned sore and that sucked up from an enlarged inguinal sore, failed to reveal a single spirochete. The preparations from the chancres were, however, crowded with minute organisms of uniform shape and character. Such an organism might be described as a somewhat thick, irregular band bent upon itself more or less so as to almost make a circle. The films from the gland (in one of the cases) showed equally numerous bodies, but in a further stage of development. In them the band had opened out and the "head" had enlarged. The proportion between "head" and "tail" varied in different cases, but various gradations were present in the same film. In another preparation from a hard chancre the same forms were seen, together with a set still further developed. Between these latter and some of the *Spirachæta pallida* there was not much difference, and the inference from the consideration of these various forms has given rise to the opinion that the *Spirochæta pallida* was merely a development of the more minute series. Further, a number of round, deeply-stained bodies were noted in considerable numbers, and some of these had invaded the red corpuscles. These bodies were filled with small granules, and when a red cell containing such an organism had been burst the débris thrown out was very like a collection of the small organisms seen in the preparations from the chancres and glands of the cases referred to. Other forms seemed to show the breaking up of the spirochetes. Their bodies are similar to those figured by Siegel, who claims specificity for them, declaring that the spirochete was merely saprophytic. MacLennan believes that one is merely the development of the other the *Spirochæta pallida* being merely one phase in the life history or perhaps a part only of the organism during one stage of its development.

The X-Ray in the Treatment of Ringworm.—G. Sichel records his results in the ray treatment of ringworm and

parasitic alopecia. He has had in all 102 cases. Of these 67 are still under observation, and no therapeutic claim is made concerning them. Of the remaining 35 cases, 30 were ringworm and 5 alopecia areata. Of the alopecia areata cases 4 are recorded as cures and 1 case was just beginning to grow but did not attend again to be seen. Of the 30 ringworm cases, 11 were cured, 10 were failures, and 9 ceased to attend before a definite result could be pronounced. Out of the whole 102, the author saw one case of ray dermatitis which he fears will result in permanent baldness. Disadvantages of the method are, the necessity of a specially trained nurse, danger of burnig, and the difficulty of regulating the ray dosage. Full details of treatment are given in its paper. Most of the failures belonged to the following type of case. There is no burn and the patient suffers no harm, but has all the bother and expense of the treatment, and still suffers from ringworm. These are cases in which the hair comes out patchily, and small scattered islets of infected hairs are still left dotted about all over the scalp. One is afraid to repeat the treatment for fear of inducing dermatitis, and when the hair grows again on the denuded areas it becomes reinfected from the older spots. When the new hair has grown considerably it is often of a different color from the old.

Aural Cases in General Practice.—Stephen Paget details some of the clinical methods he has found of service in examining ear cases. He discusses the various topics, from the standpoint of the general practitioner, and points out the fallacies of some of the conventional text-book statements. Nothing essentially new is brought forward, but the tone of the article is practical and sensible.

Berliner klinische Wochenschrift, January 29, 1906.

The X-Ray Examination of the Stomach and Its Application to the Diagnosis of Carcinoma.—Holzknecht describes observations on healthy and diseased stomachs by means of *x*-ray examinations made after the ingestion of food containing considerable quantities of subnitrate of bismuth. It was found that much more satisfactory results were obtained if the observations were made directly by means of the fluoroscope than if photography was resorted to, because the phenomena produced were so varied in nature that continued inspection was necessary in order to obtain any insight into their import. One conclusion reached was that a stomach normal in size and position is very rarely seen. The normal type of stomach is rather small and is so placed that the pylorus forms its lowest point. The form most often observed, on the other hand, is much larger and through descent of the greater curvature exhibits a rise at the pylorus. The author explains the formation of this type of stomach by the almost universal relaxation and atrophy of the anterior abdominal muscles, induced by the habits of muscular inactivity of the present age. In this way the lower part of the abdomen becomes protuberant and the pad of intestines on which the stomach normally rests drops down a considerable distance. The extremities of the stomach being fixed, while it is to a certain extent deprived of its natural support, the organ, which was not constituted for the purpose of standing a strain of this sort, undergoes gradual dilatation in the direction of its long axis. In other words, this is the beginning of gastroptosis, a condition which usually receives attention only when present to a marked degree, whereas naturally all intermediate stages must also exist. The author describes the phenomena attending the filling of the stomach with food as visible on the fluoroscopic screen, and explains the manner in which observations of this sort may be used for the detection of nonpalpable carcinomata. Owing to the infiltration of the gastric wall with the tumor masses, easily recognizable abnormalities in the behavior of the stomach when bismuth food is poured into it can readily be detected. Its functional efficiency can also be tested by inclosing bismuth in tiny bags of goldbeater's skin, which are swallowed by the patient. As soon as the bag is digested by the gastric secretions the bismuth escapes, an act which is readily discernible with the fluoroscope. The author considers that this method is superior to the somewhat similar one of Sahli.

Clinical Observations on Anemia.—Rollin has made an extensive series of parallel observations on the blood and stomach contents in various gastric disorders, and has reached the conclusion that a certain relationship exists between gastric efficiency and the condition of the blood. In cases of hyperacidity there is a reduction in the nutrition of the blood, and clinical experience has shown that the administration of dog's gastric juice was of great advantage in cases of severe anemia, probably owing to the high acidity and bactericidal power of the secretion thus introduced into the stomach.

Münchener medizinische Wochenschrift, January 30, 1906.

Intraperitoneal Shortening of the Round Ligaments.—Steinbüchel is a warm advocate of the operation devised by Menge for the correction of retrodisplacements of the uterus. The operation consists in forming a loop in the round ligament of each side and suturing the apposed surfaces of the round ligament with a continuous stitch of catgut, taking care to pass the needle only superficially, so as to avoid constriction of the main artery of the ligament. The folded portion of each ligament is stitched to the front of the uterus, as is also the fold formed in the broad ligament. Steinbüchel reports six cases treated in this way with excellent results. Most of the patients were also suffering from some other abdominal condition, which rendered a laparotomy necessary, and in one instance the patient had been suffering so severely from pain as the result of a previous ventrofixation that the laparotomy was undertaken in order to liberate the uterus from its adhesion to the abdominal wall. Menge's operation was performed and the patient completely restored to health. Steinbüchel also speaks well of the modified Alexander-Adams operation, in which the abdomen is opened by a transverse suprapubic incision, for the purpose of freeing the uterus from any adhesions, and the round ligaments are made accessible in the inguinal canal from within. Menge's operation, however, does not require any particular type of incision, can be quickly performed, and does not divert the line of traction of the round ligaments from its normal direction.

The Excretion of Uric Acid and the Xanthin Bases in the Treatment of Leukemia with the Roentgen Rays.—Rosenberger made a series of analyses of the urine in two cases of leukemia and one of pseudoleukemia that were treated by means of the *x*-ray. His observations led him to conclude that exposure to the Roentgen rays alters the amount of uric acid excreted, but a similar effect has not yet been observed in other diseases. At the beginning of the treatment the exposure to the rays increases the amount of uric acid excreted. A decrease in the amount of uric acid excreted in the course of the treatment is a favorable prognostic omen, but in relapses the amount of uric acid rises again. The excretion of the xanthin bases is increased during the treatment and its after-effects. In the case of pseudoleukemia treated, the *x*-rays apparently were not without effect on the spleen, though no curative tendency was noted and the uric acid excretion was not modified.

A Fistula Between Stomach and Lung.—Loeb's patient was a man of twenty-eight years, who for twelve years had complained of severe paroxysms of coughing, coming on usually after meals. Large amounts of expectoration containing food particles were coughed up. Examination of the expectoration showed that it was of an intensely acid reaction, and that it contained lactic acid and large numbers of long bacilli of the varjety common in the stomach in retention. After taking a meal followed by a capsule of methylene blue, the patient coughed up large amounts of blue-stained food. The author says that this is the only case on record in which a patient has survived such a condition for any considerable length of time. *X*-ray examination showed the existence of a cavity of considerable size in the right lung, which is also a rarity, as in practically all of the other reported cases the communicating opening has been situated on the left side. In the present case it is difficult to arrive at a satisfactory conclusion in regard to the etiology of the condition. One presumption is that a more or less latent ulcer at the duodenal end of the stomach perforated, and escaping material found its way between adhesions around the free edge of the liver along the anterior abdominal wall to the diaphragm, which it perforated and so gained access to the lung. On the other hand, the process may have traveled the other way, and have started in the lung either as a gangrenous destruction of tissue or as the result of a congenital malformation, though there is not a great deal of evidence in favor of either of these views. The patient's general condition was fairly good, and he was able to work, so that for the present at least no attempt at treatment, which would of necessity be surgical, was made.

Deutsche medizinische Wochenschrift, February 1, 1906.

Vaginal Cesarean Section and the Surgical Era in Gynecology.—Hofmeier deprecates the present tendency to resort to radical surgical measures in midwifery on the slightest excuse. He criticises Dührssen's operation of vaginal cesarean section both on the score of its name and of its advisability as a more or less routine measure, and suggests that it would more correctly be called colpohysterotomy. The modern trend of obstetric authorities toward what they term the surgical era in obstetrics is considered inexpedient by the author because the procedures advocated by this school are, as they themselves admit, unsuited to the usage of the general practitioner. The results obtained by the newer operative methods of delivery are not so vastly superior to those attending the older, more conservative measures as the obstetric surgeons would have us believe, and it is unwise to teach students a system which they will not be able to employ in practice. The guiding principle of the older obstetricians "first the mother, then

the child" is in danger of being reversed by these surgical enthusiasts who are almost on the point of exclaiming "first the child, then the mother." The difficulty is that the ethical considerations involved have been formulated by men, and it is more than doubtful whether if there were any likelihood of these rules being applied to their own persons it would not seem to them more desirable to save the life of the mother, even at the risk of the child's death, with the expectation that at a future period she would again be in a position to pass through the ordeal of labor more successfully.

Sahli's Desmoid Reaction.—Kaliski describes a series of observations undertaken to test the reliability of Sahli's new method of investigating gastric efficiency by the use of small bags of rubber tissue containing a small amount of potassium iodide or methylene blue and tied with a strand of fine catgut. Pills of this sort were given to thirty-nine healthy individuals, seven of whom were subsequently subjected to an examination of the stomach contents after a test breakfast. Six cases of hyperacidity, six of anacidity, two of suspected carcinoma, and three of subacidity were all tested by Sahli's method and by the chemical examination of a test breakfast. The results showed that the simple method of Sahli was perfectly reliable, and furthermore that certain diagnostic conclusions could be drawn from the length of time required for the reaction to be completed. In cases of hyperacidity a deep blue coloration of the urine appears in four to seven hours; if the acidity is normal the reaction appears in from seven to twelve hours and the urine first passed is faintly blue. In subacidity or motor insufficiency the reaction does not appear until the next day.

Acute Goiter as a Result of Seasickness.—Rosenfeld says that although the occurrence of acute goiter is not mentioned as a possible consequence of seasickness in monographs devoted to this subject, he believes that it is not a very rare complication. He describes one instance occurring in a woman of forty-five in whom in the course of about ten days the tumor reached the size of the fist and then, as the seasickness was overcome, decreased gradually in size until, at the end of three weeks, it had almost entirely disappeared. On the same voyage a much slighter degree of the same manifestation was observed in an older woman, and the author speaks of having had a similar experience related to him by another patient as having occurred on a previous voyage. Rosenfeld assumes that owing to the local hyperemia occasioned by the seasickness a true parenchymatous hyperplasia of the gland took place in the first patient. The slow subsidence of the swelling showed that it could not have been due merely to congestion or distention of the follicles with secretion.

French and Italian Journals.

Pityriasis Versicolor, Tuberculous Dermatomycosis.—Piéry and Renoux have carefully performed various experiments on animals by inoculation with scales taken from human beings. They conclude that the inoculation of the guinea-pig with the scales of pityriasis versicolor is capable of determining tuberculosis in this animal. Inoculation, however, either with the products of the scrapings of the skin of phthisical patients (whose expectoration swarms with Koch's bacilli), or with the scales of any other dermatosis occurring in the course of phthisis, does not cause tuberculosis in the guinea-pig. Pityriasis versicolor which is observed the most often in tuberculous patients does not occur without distinction in the course of various clinical forms of pulmonary tuberculosis, but almost always in the case of abortive pulmonary tuberculosis only. The writers think that the results of their work justify the conclusion that pityriasis versicolor ought to be considered as a probable tuberculous dermatomycosis. This theory constitutes an argument in favor of the saprophytic nature of the hacillus of Koch, and the mycotic nature of tuberculosis.—*Lyon Médical*, January 21, 1906.

Syphilitic Pseudorheumatism.—M. L. Galliard refers to work done a few years ago in his clinic on syphilitic pseudorheumatism. Three patients who had not suffered from rheumatism before the syphilitic infection had polyarticular disturbances coincident with mucous and cutaneous lesions of secondary syphilis. These three patients recovered quite rapidly under specific treatment. More recently, Galliard has had under his care a young man twenty-five years old who had had, before the appearance of a syphilitic chancre, a severe and prolonged acute attack of polyarticular rheumatism and gonorrhea, with no signs of pseudorheumatism. Afterwards, when pseudorheumatism developed, it presented the symptoms of a serious illness. The writer gave intramuscular injections of benzoate of mercury, and from the third day the fever subsided; on the fourth day the joints became so much better that no further anxiety was felt. On the ninth day, after eight injections of the benzoate of mercury the rheumatism being completely cured, and the syphilitic cutaneous lesions being improved, the patient insisted upon leaving the hospital. The writer has no knowledge of any recurrence of the trouble.—*La Tribune Médicale*, January 20, 1906.

Hnntington's Chorea.—Anglade recently cited the case of a patient suffering from Huntington's chorea. This infection developed at the age of thirty-five years after violent emotion. Both the mother and grandmother suffered from the same disease. The patient herself died in dementia ten years after the beginning of her illness from meningeal hemorrhage. Examination of the nervous system showed nothing of interest below the brain. There may have been slight sclerosis but it was not distinct. The dura mater and pia mater were abnormal. The nerve cells appeared intact but there was a decrease in the number of cells. The most interesting point of this examination, however, was the presence of nuclei surrounded by protoplasm which was scarcely visible. Anglade believes these to be the elements of neuroglia, and by his investigations he has been able to establish the fact very distinctly. The most important lesion in this case was noted at the knee of the internal capsule with very intense reaction in the ventricular region. —*Journal de Médecine de Bordeaux*, January 21, 1906.

Nervous Sequelæ of Epidemic Cerebrospinal Meningitis.—Chailly, in his recent thesis, has given the results of his observations of three cases of epidemic cerebrospinal meningitis which terminated in recovery. This recovery, however, was not complete, since the patients all suffered from nervous troubles after their departure from the hospital. One became maniacal, believing that he was persecuted; another was afflicted with hemiplegia; the third suffered from spasmodic paraplegia. Lumbar puncture had revealed the presence in each case of the meningococcus. Chailly is convinced that it would be a matter of interest to follow up the history of such patients, apparently cured for several years.—*La Presse Médicale*, January 20, 1906.

Clinical Studies of Raw Milk for Infants.—Concetti finds that he is able to preserve uncooked milk for a long time in the laboratory, provided it is obtained under aseptic precautions. It is not necessary that it shall be absolutely free from germs, since there are many non-pathogenic germs which cause no change in the milk. Valgussa has invented an apparatus by which the milk may be taken asceptically from the cow and preserved at a low temperature up to the time that it is bottled. It has been found that carbonic anhydride, while not destroying the bacteria, serves to keep the milk in a condition of relative asepsis, retarding the development of the germs contained in it. Syphons have been made that are easily sterilizable, in which the milk is placed, and then they are charged with carbonic acid gas, like seltzer bottles. The milk will keep at least five days under this method of preparation. The gas soon disappears and leaves the milk with its ordinary taste and consistency. The small amount of carbonic anhydride remaining keeps the phosphates in solution, and the casein is more digestible than when the milk is untreated. The milk need not be divided into feedings in separate bottles, and none need be thrown away because it has been open to the air, as it may be discharged from the syphon as needed; thus it is an economical method of preservation. The chemical, physiological, and physical properties of the milk remain unchanged.—*Rivista di Clinica Pediatrica*, December, 1905.

Use of Gloves in Obstetrical and Gynecological Work.—Vincenzo Caliri discusses the advisability of the use of gloves in surgical and obstetrical, as well as gynecological work. He has made careful experiments as to the value of the different methods of sterilization that may be used in preparing the gloves, and he gives us the information that nearly all disinfectants, corrosive sublimate excepted, do not so thoroughly disinfect that broth cultures of various microorganisms may not be obtained from them. Two methods are successful: that of washing the gloves for a few minutes in soap and water, and then using a one to one hundred solution of corrosive sublimate, and that of live steam in the autoclave. Alcohol is not successful, and at the same time the gloves are injured. He also experimented as to the injury to the gloves by the disinfection, and found that all except the soap-and-water method rendered the gloves softer and made them permeable to bacteria. Sensibility is very much diminished by the use of gloves, whether thin or thick, and hence they are a disadvantage in fine manipulations. His conclusions from all his work are that, notwithstanding their disadvantages, gloves should be used by all assistants at an operation except the surgeon-in-chief, these gloves covering the entire hand and forearm. Those of the surgeon may leave the last two phalanges uncovered to aid him in feeling the parts operated on.—*Annali di Ostetricia e Ginecologia*, November, 1905.

Book Reviews.

Stoffwechsel und Stoffwechsel Krankheiten. Einführung in das Studium der Physiologie und Pathologie des Stoffwechsels für Aerzte und Studierende. Von Dr. Paul Friedrich Richter, Privatdozent und Laboritoriums-vorstrand am Poliklinischen Institut an der Universität Berlin: August Hirschwald, 1906.

Medicine has made such extensive inroads into the several provinces of chemistry that it is almost impossible for the average practitioner to follow the reasoning of some of the advanced workers in the departments of metabolism, nutrition, excretion, etc., and their perversions. The present volume of almost 400 pages is regarded by the author as an introduction to the study of these complex problems, and though it is rather more thorough-going than its subtitle might lead one to believe, the subject is dealt with from the standpoint of the beginner and with sufficient simplicity to be really helpful to the average reader. The first 130 pages are devoted to the metabolic process of the healthy body, and in the remainder of the book the disorders of assimilation and excretion that attend disease are discussed. The volume closes with a short outline of the various technical methods used in determining nitrogen, uric acid, ammonia, etc. The only criticism that suggests itself is that the author might easily have made his work of much greater value to the class for whose benefit it was ostensibly written by introducing a little more of the clinical element and suggesting some of the practical deductions in regard to treatment that may be drawn from the more or less theoretical material set forth at such length.

A Text-Book of Physiology for Medical Students and Physicians. By William H. Howell, Ph.D., M.D., LL.D., Professor of Physiology in the Johns Hopkins University, Baltimore. Illustrated. Philadelphia and London: W. B. Saunders & Company, 1905.

In writing a textbook of physiology at the present day, an author is confronted with a bewildering number of researches, many of which are contradictory in their conclusions. One of the guiding principles, therefore, which must be borne in mind while planning a work of this character, is the need of judicious elimination. It would be simpler, perhaps, to present all the facts and theories on a given subject and permit the reader to draw his own conclusions. This would add greatly to the bulk of the volume, however, without affording a satisfactory presentation of the subject to the medical student. It is preferable to sift the evidence at hand and then to emphasize those conclusions which seem to be most justified by experiment and observation. In following out this method, a certain amount of trust must necessarily be reposed in the author, and in the present instance it does not seem to be misplaced. Dr. Howell's presentations of the fundamental facts of physiology is characterized by a simple lucid style and good judgment, which is especially noteworthy from the complexity of the subject. The arrangement of the matter is as we usually find it in the other text-books, but in addition to the older and more established views, the more modern aspects, even if still unsettled, are incorporated. This is fortunate, as the advances made in certain allied branches, especially in chemistry, have quite upset some of the theories formerly held to be incontrovertible. The student is made to realize that the subject of physiology is constantly expanding, and in order to accentuate this growth, historical résumés are introduced at suitable intervals throughout the book, which add greatly to its general interest. Dr. Howell's work can be safely recommended as a complete, well-written, modern book on an important subject.

Manual of Pathology, Including Bacteriology, the Technic of Postmortems, and Methods of Pathological Research. By W. M. Late Coplin, M.D., Professor of Pathology and Bacteriology, Jefferson Medical College, Philadelphia, etc. Fourth Edition, Rewritten and Enlarged. Philadelphia: P. Blakiston's Son & Co., 1905.

This book presents a somewhat interesting history of growth, it having been developed from a series of abstracts of the author's lectures in pathology. Part I of the book is devoted to technic and is sufficiently complete for all practical purposes, while in the appendix there are additional chapters on bateriological manipulations, and on the microscopical examination of urine and of sputum. The remaining parts of the work are given up to general and special pathology. Its scope is quite extensive and many topics are included which are not ordinarily found in books of this class. The style is concise, pleasing, and easily read. The new matter presented in accordance with the progress made by pathological science is stated to have enlarged the text one-third, and corresponding to this there has also been an increase in the number of illustrations, most of which are new and original. Another innovation consists of references in foot notes to other articles, which will afford additional information to the reader on the subject under discussion. The author intends the book neither as a treatise, nor a work of reference, but as a manual for the laboratory and post-mortem room.

Gallstones and Their Surgical Treatment. By B. G. A Moynihan, M.S. (Lond.), F.R.C.S. Second Edition, Revised and Enlarged. Philadelphia and London: W. B. Saunders & Company, 1905.

It is but recently that we reviewed the first edition of this authoritative work, dealing with a subject which only a few years ago was accorded a short chapter in works on general surgery—and a rather larger one in treatises on internal medicine. The patient with gallstones was, within the memory of even the younger practitioners of medicine, purely a "medical case." He was treated with alkalies or olive oil, or sent to Vichy, with the hope that his recurrent attacks of colic would be relieved, and a suggestion that he was a legitimate subject for the operating table would have been accredited to unwarranted surgical pretensions. Now, largely through the influence of the author of this work, the Mayos, and others, gallstone disease is recognized as a surgical affection. That Mr. Moynihan's treatise has met with ready appreciation is shown by the fact that the first edition was exhausted in a year. This has given the author the opportunity to revise his work and to add to it a review of the extensive literature that has sprung up in this brief period. This second edition does not differ materially from the first in essentials. The general principles remain the same, but the necessity of a new edition has given the author an opportunity to review what is new in his subject and to include in his work a section on the congenital abnormalities of the bile-ducts and gall-bladder.

The Management of a Nerve Patient. By Alfred T. Schofield, M.D., Author of "The Unconscious Mind," "The Force of Mind," "Unconscious Therapeutics," etc. Philadelphia: P. Blakiston's Son & Co., 1906.

There is much in this book—the whole book, in fact—that can be read with profit by the practitioners of medicine, not only the one who has to deal with the subject of functional nervous or mental disease, but the general practitioner as well. The subject matter of the monograph is the power of the unconscious mind, which the author regards as the same as our familiar old *vis medicatrix naturæ*. He complains bitterly of "the waves of psychic nonsense that flood this country [Great Britain] from America," by which we suppose he means Eddyotism, but urges his readers not on that account to reject the great fact of the influence of the unconscious mind upon the body. He shows how the physician may stimulate the unconscious mind to action and so bring into play this potent aid in the cure of functional nerve disorders. It is not only in functional troubles, however, that the mind is potent in its influence upon the body, for Zola was on the right track, in his tiresome "Lourdes," in surmising that the unconscious mind could influence for good the reparative processes even in such a purely physical disease as lupus. To the broad-minded physician, who is only anxious to cure his patient by any means, whether recognized as "legitimate" or on the confines of the illegitimate, because indefinite and not yet clearly understood, this book contains many suggestions which may be acted upon with benefit to patient and physician alike.

Vorträge und Aufsätze über Entwicklungsmechanik der Organismen. Herausgegeben von Wilhelm Roux, Heft 1. Leipzig: W. Engelmann; New York: Paul B. Hoeber, 1905.

It is Roux's intention to issue in collaboration with other investigators a series of treatises under the above title, each of which shall present in complete form certain aspects of organic development of which the essential facts have been fully established. The first issue is by the editor of the series, and deals with the "mechanism of development as a new branch of biological science." Roux believes that most works on embryology do not pay sufficient attention to this subject, and this book may serve as an addition to their text. The writer may be in reality regarded as the originator of this branch of biological investigation, which endeavors to ascertain the cause of morphological development by experimental methods. He claims, moreover, that physical and chemical laws are in themselves sufficient to account for all vital processes. The book is divided into two parts, the first of which presents a general discussion of the subject, and the second, the larger, includes a more detailed exposition of the various items, and is intended for those more especially interested in the subject. The book is intended for the biologist, and yet there are many suggestive points in the author's conclusions, which, although somewhat startling, may prove of value to those interested in the problems connected with human embryology.

Society Reports.

AMERICAN DERMATOLOGICAL ASSOCIATION.

Twenty-ninth Annual Meeting, Held at the Academy of Medicine, New York City, December 28, 29, and 30, 1905.

(Special Report to the MEDICAL RECORD.)

THE PRESIDENT, DR. WILLIAM T. CORLETT OF CLEVELAND, OHIO, IN THE CHAIR.

Address of the President.—Dr. CORLETT, in his opening address, said that while the study of dermatology in this country was awakening keener interest and was better taught than ever before, yet the character of the teaching in many schools left much to be desired. To become efficient in dermatology the concentration of clinical material was important. What a veritable Mecca of dermatology might be built up in New York City if the various diversified interests were concentrated under one well-organized institution. This applied with even greater force to clinical material in the lesser centers of population. To make these desirable changes, wise and liberal endowments were necessary. Their effect was already apparent in certain quarters, and there were hopeful signs in others. The almost general recognition of dermatology in the curriculum was an epoch in the evolution of American medical education.

Additional Observations on the Roentgen Rays in Dermatology.—Dr. HENRY W. STELWAGON of Philadelphia, Pa., said that at a meeting of the Association two years ago he gave a résumé of his experience with the Roentgen-ray treatment of various cutaneous diseases. Practically repeating, to some extent, his former conclusions, he could say now, in the light of wider experience, that we had in the *x*-rays a valuable addition to our therapeutic resources, but it was by no means a measure that should be used indiscriminately, or be permitted to supplant other methods equally useful but without possible deleterious effects; that its application should be extremely cautious and conservative in non-malignant dermatoses, and excepting in extremely obstinate cases it should be used more as an adjunct than as the sole remedy; that in malignant diseases it could be used somewhat boldly and often with the prospect of cure, or at least distinct amelioration; but that even in such diseases it might often be more advantageously employed as a helpful and supplementary measure than as the sole method of treatment.

Dr. CHARLES W. ALLEN of New York City said that, in order to learn what the *x*-rays would do in dermatology, it was necessary to rely very largely upon personal experience. He employed the *x*-ray as a therapeutic agent more than ever before, and he liked it better for certain things, but he had become convinced that it must be used with greater care than hitherto. In the treatment of acne the effect of the rays should be expended on the deep follicles and glands, and no effect on the superficial tissues was necessary. The latter could be taken care of with antiseptic washes, etc., but for the deeper structures the rays were necessary. In the treatment of skin diseases and cancers he now tried to combine different methods, so as to get the best results from all.

Dr. L. A. DUHRING of Philadelphia, Pa., said he had employed the *x*-ray treatment in psoriasis for a number of years, and, on the whole, his experience with it had been very unsatisfactory. He agreed with Dr. Allen that in order to obtain the good effects of the rays, it was not necessary nor advantageous to produce a determatis. His experience with the rays had led him to fear the superficial changes in the skin produced by that agent.

Dr. JOHN A. FORDYCE of New York City said that in the treatment of malignant disease of the face he would emphasize the value of curetting the lesion before using the *x*-rays. This was especially true in dealing with the fungating forms of epithelioma. The curettage in these cases was not done as thoroughly as it was when that measure was relied upon without the use of the rays.

Dr. EDWARD B. BRONSON of New York City said that some of the best results he had seen produced by the *x*-rays had been in acne, not of the simple type, but in cases where other methods had been unsuccessfully tried. In such cases that would not stay cured it was essential to produce a decided modification of the follicles, and that he had seen done by the *x*-rays. The proper method was to produce just the necessary degree of atrophy; a degree that would not destroy the integrity of the skin, and yet would check its morbid activity. In such cases he knew of no remedy that would compare with the *x*-rays.

Dr. JAY F. SCHAMBERG of Philadelphia, Pa., said that in the treatment of superficial epitheliomata the application of the *x*-rays was almost universally successful, and in dealing with deep, rodent ulcers about the canthus of the eye, with an excavation of tissue, it was the treatment *par excellence*, and would often effect a cure where nothing short of an extensive surgical operation would have achieved the same result.

Dr. THOMAS C. GILCRIST of Baltimore, Md., said that, as the *x*-rays possessed no bactericidal powers, we had to depend upon their destructive action for a cure of the disease to which they were applied. In acne his results had been good, although some relapses had occurred. In lichen planus he had seen cures effected very much quicker by this method than by any other with which he was acquainted. In dealing with rodent ulcer and various other forms of malignant tumors he was in favor of doing a preliminary curettage, as the *x*-ray did not have much effect upon the growth until the hard edge was broken down.

Dr. S. POLLITZER of New York City said sufficient evidence had been adduced to prove that the *x*-ray was a valuable addition to our therapeutical resources, and the discussion regarding it was in general harmonious as to its indications and advantages. The speaker briefly reported two cases of epitheliomatous growths of the mucous membrane, both of which did very badly under the *x*-ray treatment.

Dr. FRANK H. MONTGOMERY of Chicago, Ill., said that after a considerable experience with the *x*-ray he had never had any bad results from it in the way of troublesome dermatites or burns.

Dr. Stelwagon, in closing, said that in his *x*-ray work he always tried to employ the lowest current that would answer the purpose.

A Case of Tropical Ulceration Involving the Nose, Pharynx, and Larynx, with Histological Findings.—Dr. JOHN A. FORDYCE of New York City and Dr. W. F. ARNOLD, Surgeon U. S. Navy (Retired), reported this case. The lesion was a chronic ulceration of six years' duration, involving the upper lip, nares, lacrymal duct, nasopharynx, and larynx, in a negro, a native of Panama. The condition, at first thought to be syphilitic, was influenced in no manner by large doses of iodide of potassium or of mercury, given internally, hypodermically, or by inunctions. Tuberculin injections caused no reactions, nor could tubercle bacilli be found in the secretions. An inoculated guinea pig developed a folliculitis with secondary ulceration, but showed no signs of tuberculous infection. Histologically, the condition in the patient was a granuloma resembling tuberculosis.

A Case of Meralgia Paræsthetica.—Dr. JAMES C. WHITE of Boston, Mass., reported a case of a man, 55 years old, who became aware in July, 1905, of abnormal sensations in the skin of the outer lower two-thirds of the right thigh after an ordinary walk of four or five miles. The feelings were of a tingling nature. From that date, on standing or walking, this region became the seat of a variety of perverted sensations, described as tingling, tenseness, and tearing of formication. Sometimes there were darting sensations, like the bursting of a bubble; some-

times a dull, deep pain or ache when the leg was tired. They often began as a glowing sensation in the part. They generally ceased on sitting or lying down, but might recur in such attitudes on overstretching or violently twisting the leg. Deep pressure with the hand over the part might bring them on, and the patient was always aware of something wrong there on standing or walking. The sensations were felt every day, and interfered with his habits of exercise. They were somewhat on the increase. There was no pruritus nor feeling of constriction in the affected surface. On inspection it was apparent that the area complained of corresponded strictly to the distribution of the cutaneous filaments of the external cutaneous femoral nerve. The skin presented to the eye no marked differences from the corresponding region of the opposite thigh. The patient was of good habits, and had shown no indications of a faulty nervous system previously, and there had been no manifestations of organic or functional disorder, with the exception of a feeble digestion. Meralgia paræsthetica, Dr. White said, was the condition always confined to the position occupied in this case. It was first described some ten years ago by Bernhardt and Roth, and now found a recognized places in the works on nervous affections, although, apparently, of rare occurrence. We had little definite knowledge of the causation of this well-defined affection. The morbid conditions with which it was said to be often associated, namely, neuritis, tabes, rheumatism, gout, and alcoholism, were absent in the case reported by the speaker. The condition seemed to be outside the control of remedies, although massage had given partial and temporary relief in some cases.

The Incubation Period of Syphilis—Dr. Abner Post of Boston, Mass., read this paper. He stated that our knowledge of the incubation period of syphilis depended upon clinical observation, and the results of experimental and accidental inoculation. Clinical observation in this matter had the peculiarity that it was based not upon what the observer saw, but entirely upon the statement of the patient. Very few patients were at all reliable as observers: they forgot exact dates and were influenced by their own preconceived ideas. After reviewing the sources of our knowledge on this subject from accidental and experimental inoculations, Dr. Post said that the recent inoculation of the anthroid apes with syphilitic virus has opened up a new field of study. Metchnikoff and Roux had reported twelve successful inoculations, seven from human syphilis, upon chimpanzees. In these cases, the incubation period was reported in six as 22, 22, 26, 33, 35, and 37 days, an average of between 29 and 30 days, and none below 22 days. These inoculations of the human virus on chimpanzees were recognized as successful by Fournier and other competent authorities. So far as experimental inoculations were concerned, we were justified in believing that the true chancre always had a period of incubation; that the period varied within rather wide limits; that it never fell below 15 or possibly 13 days, and that 42 days was the widest limit.

Dr. J. Nevins Hyde of Chicago, Ill., said that with the aid of his colleague he had recorded more than 200 cases of physicians and nurses who had been the victims of extragenital chancres, and the period of incubation in those cases coincided very closely with the conclusions reached by Dr. Post.

Dr. Ravogli said that the incubation period probably depended to some extent upon the quality of the virus or germ with which the patient became inoculated.

Dr. Robert W. Taylor of New York City said that the cases on record in which the incubation period of syphilis was given as ten days or less were perhaps based upon the presence of broken down herpetic vesicles, which were mistaken for beginning chancre. At all events, the question would probably soon be definitely settled by the results of the experiments that were now being carried on with the anthropoid apes.

Notes on the Treatment of Epithelioma by Means of Caustic Potash.—Dr. Arthur Van Harlingen of Philadelphia, Pa., presented his communication in which he said that: (1) A certain number of cases of epitheliomata of the skin were best treated by means of caustic potash. (2) These cases comprised the small, well defined, pearly lesions, from one-half to one or even two centimeters in diameter, chiefly found upon the face and adjacent parts. (3) Larger lesions were best treated by the *x*-rays, but here caustic potash might be used to soften and dissolve the horny epithelium, and perhaps in some cases as an adjuvant. (4) In cases treated by caustic potash the use of the *x*-rays did not appear to hasten the process of reparation or to modify the cicatrix resulting from cauterization.

Dr. M. B. Hartzell referred to the beneficial effect of caustic potash and pyrogallol in the treatment of epithelioma. He first applied the caustic potash, removing it as soon as it began to smart, and then applied a 40 to 50 per cent. solution of pyrogallol.

Dr. Stelwagon said that one great advantage of the caustic potash in these cases was the rapidity of its action.

The Life History of a Case of Mycosis Fungoides.—Dr. George T. Jackson of New York City said that through the courtesy of Dr. F. S. Hope of Portsmouth, Va., he had had the privilege of noting the clinical course of a case of mycosis fungoides from its beginning to its lethal ending. The patient was an unmarried woman, 33 years old, a native of the United States, and a person in easy circumstances. Her father had an epithelioma of the face, and many of his family were rheumatic. When Dr. Jackson first saw the patient, on November 27, 1901, she was spare of flesh but in general good health. The only organic disease of which she complained was an irritability of the bladder. The duration of the mycosis was exactly five years. The disease first showed itself in August, 1900, and the patient died in August, 1905. The eruption was muscular and scaly, with but slight tendency to tumor formation. Pruritus was a marked feature of the case. The application of the *x*-rays controlled the pruritus and caused a disappearance of the lesions, but produced excessive hyperpigmentation of the skin and possibly an exfoliative dermatitis. A chronic enteritis caused death by exhaustion.

The Evolution of a Case of Mycosis Fungoides Under the Influence of Roentgen Rays.—Drs. Charles J. White and Frederick S. Burns of Boston, Mass., in this paper gave the clinical details of a case of mycosis fungoides in a man 52 years old, a farmer by occupation, and a native of the United States. The patient had always enjoyed the best of health until the onset of his present illness, in March, 1902. He was admitted to the Skin Ward of the Massachusetts General Hospital on June 26, 1905, and three days later, *x*-ray treatment was begun. The treatment was repeated at intervals of two or three days, until August 21, twenty-three exposures being given in the course of fifty-four days. The total time of the exposures was eight hours and twenty minutes. Under this treatment, in addition to local and internal remedies, the skin lesions rapidly disappeared, but coincident with their disappearance the patient suddenly developed severe toxic symptoms. He gradually lost flesh and strength, and died on September 7, 1905, apparently of toxemia. The autopsy showed a fibrina-purulent bronchitis and pleuritis; hyperplasia of the spleen and dilatation of the heart, with evidences of streptococcus septicemia, which was attributed to the formation of bed sores in the terminal stage.

Dr. George T. Elliot of New York City said he could recall several cases of mycosis in which, as in Dr Jackson's case, the fatal result was due to a chronic enteritis. In one instance, where he secured a post-mortem examination and examined sections of the various organs microscopically, he found metastases in the liver, spleen, and lungs. The question naturally arose whether the terminal diarrhea was due to a metastasis or not.

Dr. George H. Fox of New York City said the consensus of opinion was that cases of mycosis fungoides were greatly presented by the author and his colleague, Dr Ernest L.

method of treatment, he had seen the itching disappear in an incredulously short space of time, and the same was true of the tumor formation.

Dr. Charles W. Allen mentioned a case in which the treatment was begun in the premycotic stage, and the patient was now entirely well.

Dr. L. Duncan Bulkley of New York City reported several cases of mycosis fungoides that were much benefited by the *x*-ray treatment. He expressed the conviction that while this treatment relieved the symptoms, the disease steadily progressed toward its unfavorable outcome.

The Egg-Shell Nail.—Dr. J. Nevins Hyde of Chicago, Ill., said his paper was an additional contribution to the one presented by the author and his colleague, Dr. Ernest L. McEwen, at the preceding meeting of the Association, entitled, "On the Relation of Certain Dermatoses to Each Other and to Changes in Vascular Equilibrium." The title selected did not refer to any brittleness of the nail tissue, but was chosen because of the exact presentation in the nail-plates of the purplish-white hue visible on the inner face of the shell of a hen's egg. Four cases were reported as illustrative of this modification of the nutrition of the nails. The following features were common to all: The patients were all young women, below the standard of sound health. In none was there any distinct affection of the circulatory system. All exhibited marked interference with the stability of the vascular equilibrium, and all suffered from hyperidrosis of the hands and feet. In some of the cases there were distinct changes in the hue, not of the nails only, but also of the skin of the hands and feet, the bluish and purplish shades being recognized in the integument of those organs at some distance from the nails, and also in the nail-beds. The nails were thin, but never coarse in structure. There was a distinct tendency in all to curving of the nail-plate away from the axis of the bed. The changes in the nail were thought without question to be intimately associated with the hyperidorsis.

A Case of Pityriasis Rubra of Hebra's Type.—Dr. F. H. Montgomery and Dr. Peter Bassoe of Chicago, Ill., reported the case of a man, 46 years old, a farmer, whose family history was unimportant with the exception of the fact that one sister had died of tuberculosis. The patient had typhoid fever seven years ago, and for twenty-seven years had suffered more or less from asthma. For fifteen years—with the exception of six years during which he had abstained wholly—he had used alcoholic stimulants periodically to excess, indulging in sprees of three or four days duration on an average of once in ten days or two weeks. His skin disease began in February, 1904, as a large blister on the plantar surface of the right foot. This spread to almost the entire sole of the foot, and in a few days an erythematous and slightly vesicular eruption appeared on the left foot, then on the buttock, and ultimately almost the entire surface of the body was covered with a red and slightly scaling rash. For the first few weeks this gave rise to severe itching and burning. Soon after the exanthem became generalized, exfoliation was pronounced, and for the past sixteen months the skin had remained simply red and scaly, showing no other type of lesion. Two months after the eruption became generalized, the pubic hairs fell out. Those of the eyebrows were also lost, but returned. The plantar and palmar surfaces showed a markedly thickened skin. The patient died on August 22, 1905. This case, in common with others, in its clinical history and in the autopsy findings, suggested that a primary infection of the skin was the cause of, first, the cutaneous disorder; and, second, the general marasmus. It had to be admitted, however, that the etiology and patholgy of pityriasis rubra were as yet unsolved problems. The relation of the disorder to tuberculosis, suggested by Jadassohn, was not at all clear. It was highly improbable that this cutaneous affection was a rare manifestation of so common a disorder as tuberculosis, but it was quite conceivable that the marasmus accompanying the skin disease might render the patient more liable to tubercular infection. The necropsy finding did not throw much light on the nature of the skin affection, and also left doubt as to the cause of death. The conditions found suggested a terminal infection, either uremic or toxic, secondary to the skin disease.

Dr. John T. Bowen of Boston, Mass., reported a typical case of pityriasis rubra of the Hebra type coming under his observation, in which all the classical symptoms were present, up to the final stage of atrophy, which lasted for a number of years. This entire subject, he said, was still much confused.

Dr. Charles J. White of Boston, Mass., said he was present at the autopsy in the case of pityriasis rubra referred to by Dr. Bowen, and in the lung a small abscess was found which the pathologist thought was possibly tubercular.

Dr. William A. Pusey said that while many cases of generalized exfoliative dermatitis were very similar clinically, we were hopelessly confused so far as their etiology was concerned.

Dr. George T. Elliot thought that an absolute distinction should be made between cases of primary exfoliative dermatitis, and those clinical, diffuse, exfoliative processes which were secondary to other diseases. The latter had nothing in common with the pityriasis rubra of Hebra. The speaker said he was unaware, either in literature or in his personal experience, of any case of true pityriasis rubra of the Hebra type that did not result fatally, and most of them of some form of tuberculosis.

THE MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Stated Meeting, Held January 22, 1906.

Dr. Floyd M. Crandall in the Chair.

The Cold Fresh Treatment of Pneumonia.—Dr. W. P. Northrup read this paper, reporting in detail the case of a boy, aged 13 years, who developed a pneumonia, clinically of the grip type, wandering and prolonged, resolving without sputum. It began in the left lower lobe, spreading gradually to the root, advanced to the upper posterior portion, then to the apex, spreading around in front; in short it involved the entire left side. The symptoms that marked its severity were restlessness, nausea, and vomiting, delirium described as muttering, or active, nearly all the time for twelve days, incessant talking. There was also a dry tongue, moaning in sleep, picking the bedclothes, risus sardonicus, irregular respiration, irregular pulse, at times dicrotic, flushed face, and distended abdomen. The temperature touched 104° and 105° F. every day for nine days, fell a little from the ninth to the eleventh, mounted again on the twelfth, and remained normal after the thirteenth. The respirations averaged 35 to 40, by exception reached 50 or more. The pulse was seldom above 120 and usually of good character. His condition remained one of the post-typhoidal state associated with exhaustion of the cells and anemia, after the acuteness of his attack had subsided. He had illusions, delusions, etc, The boy's head was placed between two open windows, the lower sashes being opened to their utmost, the month being March. On account of the active delirium it was necessary to pass a canton flannel bandage around one ankle and fasten it to the iron bedstead. The working rule was, "Nothing between the nose and the North Pole." The room was cold, perhaps 40° F. The nurses wore heavy wraps night and day. The hot, dry skin, dry tongue, muttering delirium, limited lung capacity, called loudly for two aids, water and air. Any person looking on that boy could be easily convinced that a hot constricting poultice and vitiated air were not indicated; these would possibly have killed the child. The parents, under the influence of much explanation and observation of

the case, were convinced that the treatment fitted the indications. Dr. Northrup believed the time had come to give fresh, cool, flowing air and fresh, cool draughts of water to the stricken fevered child. It was time to cool and dilute the blood stream, aid it to unload its toxic material, to drain it from the system. It was time to lend a hand to steady the nervous regulator, to cool and bathe, soothe and refresh. In such a treatment there were no dangers; there were all advantages.

Some Problems in the Treatment of Pneumonia.—Dr. Egbert Le Fevre read this paper (see page 285).

Dr. Frank Van Fleet, father of the boy whom Dr. Northrup treated, said that whatever was done met with his approval, and he was much impressed with the treatment employed because it coincided with his own views. The recovery of the patient depended upon the condition of the heart, and when the pulse became dicrotic he said that it was a young heart and one that stood the boy in good stead. Anyone who went into the room was impressed at once with the fact that he was receiving God's oxygen and not the so-called "canned" oxygen. The boy practically received no medication.

Dr. Henry Koplik said that after listening to Dr. Le Fevre's paper he was impressed with the fact that the treatment of pneumonia was an individual one; when one treatment was proposed to be employed in all cases an error was committed, and in order to prove this he asked that the prognosis of pneumonia be considered under the so-called expectant plan. Pneumonia was more fatal in the extremes of life, whereas in midlife, between the ages of five and twenty-five years, pneumonia was one of the most favorable of diseases one had to deal with, the mortality being about 1 per cent. Dr. Koplik then referred to his continuous hospital service of four years, cases running from the ages of three months to fifteen years, altogether 83 cases with 10 deaths, a mortality of 12 per cent., all receiving the expectant plan of treatment. Among 25 cases below the age of two and a half years nine deaths occurred, a mortality of 36 per cent. There were 57 cases between the ages of two and a half years and fifteen, with only a 1 per cent. mortality. Dr. Koplik believed in fresh air, but he did not believe in chilling the patient. Children below two and a half years, especially below one year, acted badly when cold air was admitted to the room, and if a child had such a treatment as advocated he believed it would be rather heroic. The treatment was for the individual, watching the heart, conserving the patient's strength, supplying the patient with fresh, but not cold, air; by following such a method of procedure he believed we would get the best results.

Dr. Northrup said that if he was asked if he considered cold an essential part of the fresh-air treatment, he would answer yes. Cold quieted the maniacal activity. With regard to placing children under two and a half years of age in the cold, he said that Dr. Le Fevre was talking about a different kind of pneumonia. The pneumonia of children was a different thing, with a different prognosis and different behavior. They had new hearts. Take any child with a fever, if too hot, cool him; let cool air on him. At the Presbyterian Hospital all patients with pneumonia were sent to the roof and remained in the open for from four to six hours a day.

Dr. Egbert Le Fevre said he had experience with the open-air treatment of pneumonia, and he saw bad effects result only when the temperature of the air was low, as below 50°. If a stove was introduced into the room and the temperature of the room kept above 50°, the patients did better. He believed in fresh air, but not in cold air. The latter he did not believe to be an essential part of the fresh-air treatment. Experience in the treatment of tuberculosis had proven that. Dr. Le Fevre said there seemed to be a general tendency to consider that the expectant plan of treatment was the do-nothing treatment in the early stages of the disease. The older practitioners overtreated pneumonia, and yet many of their cases were carried through the disease successfully and the mortality in the earlier days compared favorably with the so-called ultra-expectant plan of treatment.

The Very Early Diagnosis of Tuberculosis by the Direct Skiagraphic Ray (X-Ray) with Stereopticon Demonstration.—Dr. Lewis G. Cole said that various attempts had been made to use the *x*-rays in the diagnosis of pulmonary lesions with more or less success. Dr. Williams of Boston had done more than any one else in fluoroscopy of the chest, making charts of the size and position of the heart, enlarged glands, and more advanced tubercular lesions; and Dr. Hultz and others had done some very good work in the diagnosis of tuberculous lesions by skiagraphs or *x*-ray pictures, and some time ago he made some skiagraphs of the more advanced tuberculous lesions. This was only partially successful, as there were other ways of diagnosing these conditions when they reached the more advanced stages. It was not until he had separated the rays into two distinct varieties, direct and indirect rays, that they were able to get the definition of the soft parts that enabled one to make the very early diagnosis of pulmonary tuberculosis. This he described in full in the May, 1895, issue of the *Archives of the Röntgen Ray,* and with this ray, which he described very briefly, they were able to show not only the bones, but the muscles, fat, connective tissue, kidney, and even the blod in the veins, and with this ray the lung, bronchi, and blood-vessels showed very distinctly. When so much detail was shown it was difficult to interpret the findings, and to aid in doing this he had made skiagraphs of a number of lungs post mortem, detected the tubercles, cut down upon them, and had them examined. Apparently from the plates the lesions began at the root, *i.e.* there were usually a number of old tubercles along the bronchi leading to the point of consolidation. A large percentage of the cases examined showed tubercles in one stage or another, a fact which he believed to have been verified by pathological findings. The principal difficulty was then in determining whether they were in an active stage or not. This could be partially determined by a single skiagraph, and when they had had more experience in reading the plates it might be determined quite accurately. In the cases where this could not be determined by a single skiagraph, a second might be made later, and if the individual tubercles had increased in size or number, one knew the process was in an active stage. Dr. Cole then proceeded to show the slides and demonstrated the direct, the indirect, and secondary rays upon the screen.

Dr. Lewis Fox Frissell said that the cases had been sent to Dr. Cole after the most careful physical examinations had been made of them, and afterwards they had compared the results. In general all of the advanced cases the physical examination and the skiagraphic findings agreed. In the early stages a large number, about 75 per cent., of the physical examinations agreed with the skiagraph, but there were other tuberculous lesions that they were unable to locate. He said he was very much impressed with the interpretations of the skiagraph, but it should be remembered that only men of experience in *x*-ray work should conduct the examinations, or else they might be misleading.

Proposed Amendments to the By-Laws to Conform with the Medical Society of the State of New York.—Dr. Egbert Le Fevre moved that the amended By-Laws, as presented, printed copies of which were in the hands of all members, be accepted. This was unanimously carried.

Warts.—Morison recommends:

℞ Hydrarg. chlorid. corrosiv.....gr. v.
Acid salicyl.....℥i
Collodion,.....℥i.

Sig.—Apply once a day, the crust formed by the previous layer being first removed. If necessary the mercurial salt may be increased up to 30 grains.—*Clinical Journal.*

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, Held January 18, 1906.

DR. CHARLES L. DANA, PRESIDENT, IN THE CHAIR.

The Treatment of Graves' Disease by a Specific Serum,—Dr. JOHN ROGERS read this paper. He said the most generally accepted theory of the direct causation of the symptoms of exophthalmic goiter was over-activity of the thyroid gland, and the active portion of its secretion was similarly believed to be a globulin containing iodine, called thyreoglobulin. In the attempt to neutralize this secretion, or check its production, several schemes for serum or allied methods of treatment had been tried. Among those might be mentioned the serum of thyroidectomized dogs, drawn after the animal had been operated upon and had developed symptoms of thyroidism; the serum of a patient suffering from fully developed myxedema; the serum and the fresh and dried blood and the fresh and dried milk of the thyroidectomized goat, commonly known as Möbius's serum; the serum of herbivorous animals which had been fed for varying lengths of time upon the thyroid glands of animals of another species; and the serum of animals into which emulsions of the thyroid glands of another species had been injected. Conflicting results had been reported for all these, but they generally agreed in a failure to cure. While assisting last year on the clinical side of the work in some experiments for the production of cytotoxins, conducted by Dr. Beebe in the laboratories of the Cornell University Medical College, he said he was greatly impressed with the specific symptoms of a nephrotoxin which he had made from dogs' kidneys. The principle seemed directly applicable to the treatment of exophthalmic goiter, and as he obtained at this time two of what were clinically and in the gross the large, soft, cellular thyroids of Graves' disease, he induced Dr. Beebe to make from this material a thyroid cytotoxin for man in the same manner as he had already made the kidney cytotoxin for the dog. The glands were ground to a pulp, extracted with normal salt solution, and the coarse fibers strained off The rather thick, cloudy filtrate was then made frankly acid with acetic acid, and a heavy precipitate of nucleoproteids resulted. The supernatant liquid was then siphoned off and half saturated with ammonium sulphate, which carried down the remaining nucleoproteids and the globulins, including the thyreoglobulin, or supposed active secretion of the thyroid gland. These precipitates were combined, and after removing the normal salt by dialysis, were to some extent injected while fresh into rabbits. The major part of the precipitate was, however, dried for preservation. The rabbits showed a severe reaction to those injections, and some died. After about five weeks of this treatment the rabbits were bled to death from the carotid and the serum thus obtained from these first inoculations he called Serum A. Serum B was made from the dried precipitate, then four months old, of nucleoproteids and thyreoglobulin combined from these diseased glands. The powder was dissolved in normal salt solution and injected as before into rabbits, but the demand for the finished product was urgent and somewhat more haste was employed than in the preparation of Serum A. The preparation of Serum C in a similar manner was begun a month later, or when the dried powder was about five months old, and when the animal inoculations were conducted with care and slowly, but with as little of the original material as would produce a reaction, as by this time its value was becoming apparent and the quantity of the dried precipitate very much decreased. Serum D was made from the normal human thyroid gland as obtained at autopsy, and had not proven satisfactory. The glands were removed several days after death, were ground to a pulp, extracted with normal salt solution, and the liquid strained through gauze. The filtrate was then made acid with acetic acid, and as very little precipitate resulted, dilute alcohol was added. The precipitate thus finally obtained was suspended while fresh in normal salt solution and injected into rabbits at intervals of about five days for some four weeks. The animals showed little or no reaction to the treatment with this material, and thus presented a noticeable difference from the previous experience. He then reported ten cases treated with Sera A, B, and C, with the result of three apparently perfect cures, three rescued from a critical condition and now approaching a cure, and the others more or less improved. After briefly summarizing the present knowledge of, and experience with, this remarkable serum, he said the experiments were admittedly very incomplete and unsatisfactory. It required weeks to prepare the serum and months to observe its effect, and as the subjects all had to be human and the medicament was evidently dangerous, its administration had to be conducted very carefully and slowly.

Preparation of a Serum for Treatment of Exophthalmic Goitre.—Dr. S. P. BEEBE presented this communication. He said that the fundamental ideas for serum therapy in this disease were, first, that the symptoms were caused by a hyperactivity of the thryoid gland, and, second, that the physiological action of the thyroid secretion was to neutralize some toxin arising in the course of metabolism. With our present knowledge the thyroid origin of the disease seemed to be the most rational of any thus far proposed. It was found that thyroid extract aggravated the symptoms in nearly every case, and attempts had been made to neutralize the products of the excessive activity of the gland by providing an oversupply of the toxin with which it was supposed the thyroid secretion normally combined. Theoretically the blood of animals which had been deprived of the thyroid gland should contain an excess of the metabolic toxin, ready for combination with the thyroid secretion, consequently the serum of thyroidectomized dogs was used both orally and by hypodermic injection, and this seemed to give beneficial results. More recently a serum obtained from thyroidectomized sheep had come into general use, and was now a commercial product sold under various names. Some favorable results had been reported from its use, but in the hands of most observers the treatment had not been of marked benefit. However, the nature of the toxin and its presence in the serum of thyroidectomized animals had not been satisfactorily investigated. A summary of the more important experimental studies of thyroid cytolysins gave an uncertain basis for clinical application. Attempts had been made, however, to produce cytolytic serum having therapeutic value in the treatment of exophthalmic goiter. The reader of the paper said that the serum with which his experiments were made was developed by injecting the nucleoproteids of some organ, such as the liver or kidney, instead of the whole organ ground to a pulp. The reasons for selecting the nucleoproteids for this purpose were obvious. The nucleus was the most important morphological and physiological part of the cell. If its specificity was a function of any of the cell constituents, the nucleus must be the most intimately concerned therein. He thought that by using only the neucleoproteids in the development of the serum, a considerable amount of extraneous material had been excluded. Because of the biological differences in proteids it was necessary to develop the serum from the proteids of the same species of animal as were used later for testing its activity; that is, nucleoproteids from the dog organs were injected into rabbits at seven-day intervals until five injections had been made, and the serum from these rabbits was then tested on dogs. Such a serum could not be expected to have much effect upon cats or guinea pigs. Test-tube reactions showed that serum made from nucleoproteids was much more specific than that made from the full cells. The results obtained by the biological test showed that such a serum was highly specific in its action. If the serum had been developed by injecting nucleoproteids from the dog's liver, it was found that its administration made the animal very sick, and if the dose had been as much as 2 c.c. per kilo, the result was fatal. On post mortem the liver was found badly damaged, while the other viscera

had not been injured. Observers had found that a serum made from liver pulp invariably caused lesions in the kidney, with albuminuria. The serum made from the nucleoproteid had not produced renal lesions, and at no time had there been albuminuria following its use. If the serum had been developed by the injection of kidney nucleoproteids, its administration caused an acute nephritis which might be quickly fatal. In some cases the nephrotoxin was given in small repeated doses intraperitoneally, and in others in one large dose intravenously. In the latter case the animal showed an immediate reaction, but in ten hours had completely recovered and remained normal for from three to five days. At the end of this time a slight amount of albumin appeared in the urine, and by the eighth or tenth day the animal had a severe nephritis. The days which elapsed between the administration of the serum and the appearance of the albumin formed the latent period. Antisera made by the injection of nucleoproteids were not absolutely specific, for they had a weak hemolytic and hemagglutinative action. He next determined to work on the preparation of a serum which would have cytolytic action on the human thyroid gland and therefore be of therapeutive value in Graves' disease. He isolated in pure form the nucleoproteids and thyreoglobulin from two glands in Graves' disease, obtained at autopsy. The method of isolating the nucleoproteids was the same as that followed in the work upon the organs of dogs. The globulin was precipitated by half-saturation with ammonium sulphate and, after filtration and washing, the excess of salt was removed by dialysis. Some injections were made from the fresh proteids, but the larger portion was dried at low temperature for preservation. A mixture of the two proteids was injected into rabbits. The nucleoproteids were included in this mixture for the purpose of producing cytolytic effect on the thyroid gland and the globulin, with the hope of developing an antitoxin to counteract the toxic symptoms. He thought it not unreasonable to conclude that the nucleoproteids were as intimately concerned in the production of thyreotoxin as they were of hepatotoxin and nephrotoxin. He thought that the results of the therapeutic application of the serum were more than coincidence, and that an impartial consideration of the clinical evidence must lead to the conclusion that improvement and recovery had been caused by the administration of the serum. The physiology and pathology of the thyroid gland were so obscure that such a means of treatment as the employment of a cytolytic serum could not be applied, as yet, with a high degree of intelligence. An active antiserum made from human tissues was capable of doing a great deal of harm, and had to be applied with a great deal of caution. The therapeutic dose was a very small one. He did not claim that the serum was absolutely specific, for he had only the clinical evidence, backed by the analogy with the hepatotoxin and nephrotoxin, which was imperfect because those were developed from nucleoproteids alone, while the thyreotoxin had come partly from the globulin injected.

Dr. W. Gilman Thompson said that he was familiar with the experimental work and brilliant results that Dr. Rogers had obtained, and he regarded the whole work as belonging to the highest type of scientific research. Personally he had seen eight or nine of Dr. Rogers's cases, several of whom had been under his general personal care. Dr. Rogers referred more to the method of preparation of the sera, and therefore he wished to speak on the clinical side. One patient, now in the Presbyterian Hospital, was expected to die within twenty-four or forty-eight hours, and they did not believe the use of the serum would be of any benefit. The patient was given three doses. The temperature was 104°, the pulse 140, and respirations 44. She was in such a toxic or septic state that the condition resembled very strongly one of malignant endocarditis. Within forty-eight hours, after two injections of the serum, she improved so rapidly that it resembled the improvement which came in a pneumonia during defervescence. She made almost a complete recovery and was now up and about the wards. Another patient with an enormously dilated heart, with a variety of murmurs depending upon this dilatation, bradycardia was produced by the initial dose given.

Symposium on the Sale and Use of Secret Medicines and on the Impure Drugs of the Shops, with Presentation of Resolutions.—Dr. Geo. L. Peabody first introduced this resolution.

Whereas, The evil caused by the widespread use of preparations of drugs of unknown and deleterious constituents inflicts a very great and growing injury upon a large portion of the public; and

Whereas, It is impossible to overcome this evil by individual effort alone because the preposterous and extravagant claims made by their purveyors are convincing to the uninformed by reason of the media of their advertisement, which include periodical literature of all descriptions, not only the daily press and magazines, but also religious and otherwise reputable medical journals and many counterfeit imitations of the latter, to some of which an income practically amounting to a subsidy is plain; and

Whereas, Physicians frequently aid in the propagation of the evil by prescribing secret medicines and by writing testimonials in favor of them, or indirectly by their failure to prescribe according to the needs of their individual patients; therefore be it

Resolved, That this Academy urge most strenuously upon its Fellows and upon all other physicians, never, under any circumstances, to sanction the use of any preparation the nature and quantity of whose ingredients are unknown to them, whether it appear in the guise of a medicine, a food, or as application for external use; and to this end to prescribe definitely, exactly, and in writing for every patient who needs any drug or combination of drugs; to diffuse among the laity as widely as possible a knowledge of the potential evil residing in preparations of drugs of unknown constituents; to second as far as therein lies the efforts of the American Medical Association in its attempt to combat this evil through the agency of its Council on Pharmacy and Chemistry, whose duty it is to investigate unofficial preparations and to publish the truth about them; and to use all proper influence to have advertisements of them removed from medical journals.

Resolved, That pending repressive legislation, which is likely soon to take place in many State legislatures and also in Congress, the attention of the State Board of Health be respectfully directed to the admirable chemical work which has been conducted for years by the Massachusetts State Board of Health and which has resulted in the filing in the Massachusetts State House of a long list of conspicuous fraudulent preparations, with a statement of the exact amount of their noxious ingredients; and that the Health Department of this city be respectfully urged to exercise its powers to protect the public against the dangers of secret preparations of all sorts which are known to be noxious or which can by chemical analysis be shown to be so, by absolutely prohibiting their sale within the limits of its jurisdiction.

Resolved, That wide publicity be given to these preambles and resolutions under the direction of the Council, and that attested copies of them be sent to the boards of health of this State and of this city.

Dr. Peabody then moved that this resolution be referred to the Council for action and report. This was seconded. Dr. Peabody thought it wise to refer briefly to the harm that came from continuing the sale of certain secret preparations and the consumption of them by the community, and he quoted the findings in the analyses of patent medicines, rather startling in nature, as reported by the State Board of Health, Public Document No. 34, Commonwealth of Massachusetts. Dr. Peabody thought the Academy had been somewhat remiss in not throwing more light on the drug subject before, and he hoped that the State and City Health Boards would help in this work. An enormous amount of capital expended in advertising would make

the work a very difficult one. One wholesale drug house told him that it spent yearly $300,000 in advertising. It was high time that knowledge be diffused upon a question which was so vital to the public.

Dr. W. Gilman Thompson said that similar resolutions had been offered in different parts of the country, and he hoped for some restrictive legislation, and if the resolutions as offered were passed practical results would accrue. If legislation at Albany was needed it should be brought there very soon.

Dr. E. Eliot Harris said that the general public, and the medical profession in particular, were more alive to-day than at any time in the past, to the injury of the health and the consequent suffering of the individual produced by the enormous consumption of nostrums or quack medicines. The ideas expressed in the resolutions should be carried out by all physicians in the interest of the general public and to further scientific medication as applied to the patient. Nostrums, secret proprietary remedies, and quack medicines were the synonyms of all the preparations presenting false statements as to their composition and fraudulent claims as to their efficacy or therapeutic value. Such were the many secret proprietary mixtures or synthetics offered to the general public and also to the medical profession, and both should beware of them in whatever guise they might be exploited, even to the disgracing of many honored names in their advertised testimonials. These nostrums were often spoken of as so-called patent medicines, which had led to considerable confusion, as was evidenced in the literature upon the subject. All samples of secret medicines should be deposited in the trash-basket, as every scientific physician should know the quantity of the ingredients in internal and external mixtures which he used, and should beware of secret synthetics.

Dr. Herman M. Biggs said that the Health Department began three years ago to take up the investigation of the character of the drugs dispensed, their activity, substitutions, and accuracy as to weight. About two years ago the Health Department had established a general drug department for the supply of their own hospitals, and in connection with it they took up the analysis of the various preparations, especially the crude drugs as sold by the large drug houses of the city.

Messrs. Hirschman and Atkinson, chemists of the Health Department, described the work done by the Department of Health in analyzing crude drugs and various preparations, such as aconite, belladonna, digitalis, and many of the coaltar preparations.

Dr. Charles L. Dana then put the resolutions to the Academy for action, and they were unanimously carried.

Dr. W. Gilman Thompson then offered the following resolution, which was unanimously carried:

Resolved, That the Council of the Academy be directed to maintain familiarity with the subject of the legislative control by the State of New York of the sale of patent medicines and proprietary medicines and nostrums, and to exercise its judgment regarding the lending the influence of the Academy to any proper measure which may be directed toward securing such control.

Phenol Camphor.—The mixture of equal parts of pure carbolic acid and gum camphor produces a clear, colorless, cily fluid, non-caustic, apparently non-irritating, miscible with alcohol but not with water, and possessing strongly the odors of its components. Chlumsky has been using the mixture of phenol and camphor for five years, in a wide variety of accessible surgical infections. Thus, he employs it freely as a surface dressing in erysipelas, lymphangitis, furunculosis, and after incisions of panaritia, phlegmons, pustules, etc. Abscess cavities and sinuses may be freely packed with gauze soaked in phenol-camphor. Chlumsky claims that suppuration is rapidly cut short, only a mucoid discharge remaining, and that there are no symptoms of poisoning.—*American Journal of Surgery.*

EPIDEMIC CEREBROSPINAL MENINGITIS.*

CLINICAL REPORT AND ANALYSIS OF SPECIAL SYMPTOMS IN THIRTY CASES, WITH REMARKS ON THE TREATMENT.

By WILLIAM M. LESZYNSKY, M.D.,

NEW YORK.

VISITING NEUROLOGIST TO THE LEBANON HOSPITAL; CONSULTING NEUROLOGIST TO THE MANHATTAN EYE AND EAR HOSPITAL AND THE HARLEM HOSPITAL.

During the recent epidemic, upwards of fifty patients were admitted to my service in the Lebanon Hospital as cases of cerebrospinal meningitis. Twenty or more of these cases are omitted from this report, as they were either of the tubercular type of meningitis, or chronic cases of cerebrospinal meningitis admitted in a moribund condition at an advanced stage of the disease. The histories and charts of others were unfortunately lost or destroyed in transportation. I am enabled, however, to present the complete records of thirty patients. In all but one the diagnosis was confirmed by the demonstration of the diplococcus intracellularis meningitidis in the cerebrospinal fluid. In the exceptional instance (Case 8) lumbar puncture resulted in a "dry tap," but in this case more than the usual array of symptoms were present.

In this series of cases nearly all types of the disease are represented, and some unusual features are noted. Of the thirty patients, 17 were males and 13 females. Fifteen recovered and fifteen died, making a mortality of 50 per cent. Three children were of one family (two died, 10, 15), and two sisters of another (one died, 3). A boy seven years of age (Case 7) during the chronic stage of the disease developed measles and bronochopneumonia, from which he recovered; but the meningitis continued and he died on the three hundred and seventh day. A boy thirteen years of age (11) recovered and was discharged. Six weeks later he was readmitted with another attack from which he made a complete recovery. (Patient exhibited.) But few such cases are on record. In the report of the Massachusetts epidemic, there was no history of a previous attack. The ages ranged from 16 months to 27 years, the average age being over 11 years. Two were infants 16 and 18 months old, respectively. Both died. The average duration at the time of admission of those who recovered was three days. One was admitted on the twenty-eighth day. Five of these patients (4, 9, 10, 12, 23) developed during the course of the disease a mild type of acute nephritis lasting from three days to several weeks.

In the fatal cases, the duration of the disease at the time of admission averaged about five days. Several were admitted on the first, second, or third day. The time from the onset of the attack until death ranged from five to forty-five days. One patient (7) was admitted on the forty-second day and died on the three hundred and seventh day. Autopsies were not permitted. The only fatal visceral complication was pulmonary edema, which was the immediate cause of death in three cases (24, 25, 26). In one (24) the edema was preceded by bronchopneumonia. The others died from exhaustion.

It has been erroneously assumed that cerebrospinal meningitis does not come within the domain of the neurologist, as it is an acute, infectious disease. It seems to me that to any unprejudiced mind, such a *noli me tangere* assumption is altogether unwarranted, for, of all diseases (regardless of etiology) it is definitely and almost exclusively a process primarily involving the cerebral and spinal meninges, in most instances producing a meningoencephalitis or meningomyelitis, increased intracranial pressure, and frequent implication of the cranial and spinal nerves. It is thus, par excellence, a disease of the nervous system. Whatever sequelæ arise, they are usually secondary to the alterations in the nerve structures. As compared with other acute infections, it is surprising that the infectious process so rarely attacks the viscera, and, as Councilman has shown, "the diplococcus does not produce a general septicemia."

All of these facts have been abundantly demonstrated by clinical and post-mortem evidence.

The following histories are classified in two groups, Recoveries and Deaths. They are numbered in reference to the date of admission to the hospital.

I also take pleasure in exhibiting eight patients who have made a complete recovery.

RECOVERIES.

Case II.—Annie G., age eleven years. Admitted April 6, 1905. Discharged, recovered, May 18, 1904. One week ago, headache and vomiting; chilly sensation alternating with fever; rigidity of neck and muscular twitching. On admission, in stuporous condition, with general prostration and involuntary urination. T. 104°; P. 120; R. 28. Pupils equal, slow reaction to light, ocular fundi normal. Tongue brown and dry; neck rigid; Kernig and tâche present; knee-jerks absent; no Babinski. Thoracic and abdominal organs normal. Urine examination negative; cerebrospinal fluid, 30 c.c., diplococcus meningitidis present. No blood examination made. Two days later, 30 c.c. of a one per cent. lysol solution was injected into the spinal canal without result. The above-mentioned symptoms continued unabated for three weeks, the temperature ranging from 100 to 103.5°, P. 100 to 130. Improvement then began, and she made a complete recovery. On the 27th of April the temperature became subnormal, and remained between 97° and 98° until the day of her discharge.

Case IV.—Rosaline D., age 17 years, clerk, single. Admitted May 2, 1904. Discharged, recovered, July 17, 1904. One brother died of c. s. m. several years

*Read before the New York Neurological Society, January 2, 1906.

ago, and her sister, admitted at the same time as patient, also died of the same disease. Five days ago, severe headache, incessant vomiting, and prostration, followed in twenty-four hours by diplopia, ptosis of right eye, stiffness and pain in neck, anorexia, and constipation. On admission, fairly well nourished, restless, and irritable; pupils equal, reaction normal; incomplete paralysis of right third nerve, as shown by partial ptosis and divergence; ocular fundi normal; cervical rigidity and retraction of head; rigidity of all extremities; knee-jerks feeble; Kernig present; Babinski absent. Heart, lungs, and abdominal organs showed nothing abnormal. T. 100.8°; P. 100; R. 24. Blood, hmg. 80 to 90 per cent. Leucocytosis, 23,000. Urine, normal. C. s. fluid, diploc. meningit. present. The above-described symptoms remained unchanged for four days, excepting rapid fluctuations in the temperature (from 99 to 103°) and the appearance of an erythematous rash on the anterior surface of the chest, abdomen, and the left arm, which lasted twenty-four hours. All symptoms then became less marked, and subsided by the fifteenth day, the temperature returning to normal. She then complained

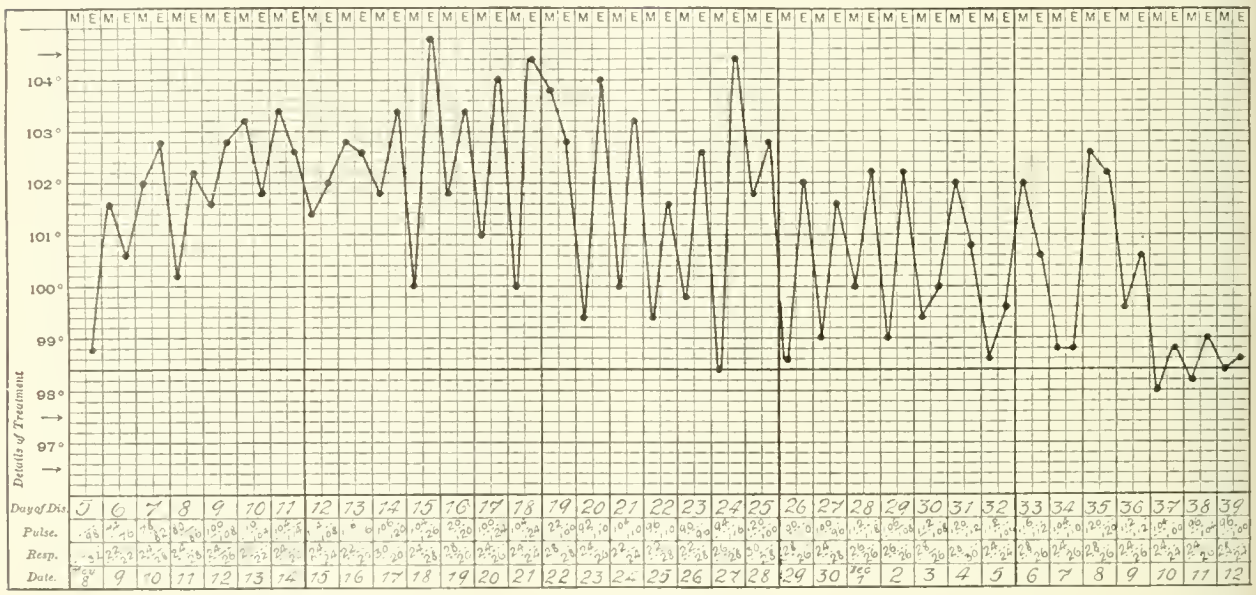

Chart 1.—Case X.

of left earache (but there was no apparent involvement of the drum) soon followed by complete deafness on the same side, which still persists. Six weeks after the onset of the disease, the urine showed all of the characteristics of an acute nephritis, without disturbance of her general health other than occasional nausea and slight vomiting. At the end of two weeks this had entirely disappeared. She made a complete recovery. The only sequel was unilateral deafness. She is otherwise in good health.

Case V.—Annie E., age 6 years. Admitted May 22, 1904. Discharged, recovered, July 6, 1904. Five days ago weakness and cardiac palpitation, anorexia, high fever, and restlessness. On admission, screams frequently; delirium, alternating with stupor; pupils equal, reaction normal; ocular fundi normal; herpes labialis; rigidity of neck; knee-jerks absent; Kernig present; no Babinski. T. 103°; P. 120; R. 30. Heart, lungs, and abdominal organs normal. Urine, negative. No blood examination. C. s. fluid (11 c.c.), diploc. meningit. present. During the following three weeks her condition remained about the same, with occasional general convulsions and delirium, and frequent exacerbations of temperature from 99° to 104° or 105°, and rapid pulse. From time to time, urine was passed involuntarily. Gradual improvement then began, and she made a complete recovery.

Case VIII.—Annie K., U. S., age 16½ years, shopgirl. Admitted September 22, 1904. Discharged, recovered, October 13, 1904. Three days ago, headache and pains all over the body, especially in the lumbar region; acute constipation; vomiting continued for two days. Twelve hours later she became very restless, then stuporous and delirious, and did not recognize her mother or her surroundings.

On admission, semicomatose, but could be aroused; nutrition good; menstruating; herpes labialis; dysphagia. Heart, systolic hemic murmur at base; lungs normal; spleen slightly enlarged; T. 104.6°; P. 116; R. 24; loss of vesical and rectal control; pupils equal, moderately dilated, reaction normal; ocular fundi normal; tongue coated and moist; pronounced rigidity of neck and retraction of head; knee-jerks absent; Kernig present; plantar reflex normal; petechial eruption about both knees. Urine, normal. Leucocytosis, 20,400. Lumbar puncture, "dry tap." Two days later consciousness returned and she was able to swallow. The temperature continued between 100° and 104°. Pulse from 94 to 144. At the end of a week improvement began, there was restoration of bladder and rectal control, the knee-jerks returned, and the temperature was practically normal on the fourteenth day of the disease. Recovery was rapid, uninterrupted, and complete.

Case IX.—John P., U. S., age 19, plumber. Admitted October 28, 1904. Discharged, recovered, January 16, 1905. Two days ago, chill and severe headache; vomited twice; was restless and delirious, and at times violent, mumbled continuously, and rapidly lapsed into stupor. On admission, semicomatose, very restless, calls out and screams at intervals; has visual and aural hallucinations; loss of vesical and rectal control; rigidity of neck and retraction of head; pupils equal, reaction normal; ocular fundi normal; tongue moist, brown, and coated; herpes labialis; knee-jerks normal; Kernig and Babinski present; petechiæ over elbows, knees, and epigastrium; T. 98°; P. 90; R. 30; heart, lungs, and abdominal viscera normal. Urine contains albumin 30 per cent. by volume, hyaline, and granular casts.

Leucocytosis, 42,000. C. s. fluid, diploc. meningit. present. At varying intervals during the following four weeks complete return to consciousness occurred for several days at a time, when rigidity of the neck would disappear. At other times, he complained of severe frontal headache, had violent de-

Chart 2.—Case XI. First Attack.

lirium, in which he screamed and sang, and had visual and aural hallucinations; rectal and vesical incontinence; twitching of facial muscles and extremities; occasional vomiting; horizontal and vertical nystagmus, and rapid emaciation. The temperature fluctuated between 99 and 102.6°. Pulse rapid. All of these symptoms subsided at the end of four weeks, but Kernig's sign persisted for several weeks longer. The nephritis gradually disappeared, and the urine was normal December 10. Three times from 30 to 50 c. c. of cerebrospinal fluid were withdrawn without relief. On November 19, 20 c. c. of 10 per cent. lysol solution was injected into the spinal canal, and improvement soon followed.

Case X.—Mollie S., U. S., age 27, stenographer. Admitted November 8, 1904. Discharged, recovered, January 24, 1905. Five days ago, chill, followed by frontal headache. The next day, headache, and vomited several times; anorexia; constipation; general hyperesthesia; fever; irritability; prostration; apathy; rigidity of neck, and stiffness of both hip-joints. On admission, semicomatose, mild delirium; sighing respiration; menstruating. Pupils equal, no reaction to light, ocular fundi normal; neck rigid; knee-jerks absent; Kernig's sign could not be satisfactorily determined on account of pain on movement of knee-joints; plantar reflex absent. T. 98.8°; P. 98; R. 32. Heart and lungs showed no evidence of disease. Leucocytosis, 32,000. C. s. fluid (20 c.c.), diploc. meningit. present. November 10. Herpes labialis; slight horizontal nystagmus; neck very rigid; Kernig present; petechiæ and erythema about elbows and knees; occasional transient rigidity of extensors in right upper extremity; both knee-jerks active, right pseudoclonus. Condition otherwise unchanged. Urine, acid, sp. gr. 1035, albumin, 8 per cent. by volume, hyaline, and granular casts, red blood-cells and leucocytes. November 11. Both lower extremities were held rigidly extended, and a slight arthritis developed in both knee-joints. Involuntary urination. November 12. Sensorium clearing. Pupils equal; no reaction to light; hyperesthesia in lower extremities; petechiæ well-marked at ankles, knees, and elbows; swelling of knee-joints has subsided. After this she was delirious from time to time, was very restless, and urine was discharged involuntarily; at other times she was rational and complained of headache. November 21. Severe chill. T. 104°; P. 136; R. 36; followed by active delirium. November 26. Chill, headache and vomiting. December 12. Condition much improved; mind clear; general emaciation; very little rigidity of neck; pupils normal; knee-jerks have returned; Kernig present. All symptoms gradually subsided. The urine contained albumin and casts for nearly three weeks, but became normal on and after December 7. During the course of the disease she had two mild attacks of epistaxis. Lumbar puncture was done three times, and from 30 to 50 c.c. of fluid withdrawn. All specimens contained the diplococcus intracellularis meningitidis. She made a complete recovery, and has remained in perfect health to the present date, nearly one year since attack.

Case XI.—Emil S., German, age 13, butcher's boy. Admitted November 21, 1904. Discharged, recovered, December 25, 1904. Three days ago severe frontal headache, fever, and vomited several times. Restless; irritable; refused food and moaned continuously. Subsequently, chill, lasting ten minutes, followed by high fever, delirium, stupor, and great prostration. On admission, well nourished; face pale; active delirium most of the time, with occasional moments of clear consciousness; general hyperesthesia; pupils contracted, equal, no reaction to light; tongue moist and coated; marked rigidity of neck, with retraction of head; knee-jerks absent; Kernig, Babinski, and tâche pres-

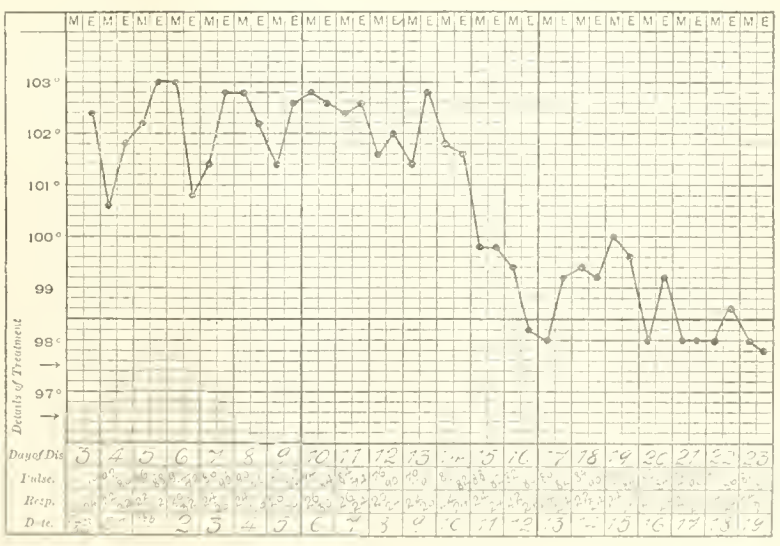

Chart 3.—Case XI. Second Attack.

ent. T. 104.2°; P. 106; R. 30. Heart, lungs, and abdominal viscera normal. Urine, negative. Blood, w. b. c. 14,000. C. s. fluid (25 c.c.), diploc. meningit. present. The symptoms continued unabated, but with less frequent delirium. On the eighth day he complained of severe pain in both knee-joints,

which was aggravated by movement, but there were no other signs of arthritis. This subsided in a few days. In attempts to demonstrate Kernig's sign, it was found that both sciatic nerves and the muscles over the loins were very sensitive to pressure, a phenomenon which continued throughout the attack.

All symptoms gradually disappeared, the temperature became normal on the fourteenth day, and he made a complete recovery. He was kept in the hospital until December 25, when he was discharged. He returned at once to his customary work as a butcher's boy, carrying heavy baskets and doing rough work in general, and remained perfectly well until January 28, 1905 (forty-five days after recovery from the first attack), when he was suddenly seized with severe headache, fever, delirium, and general hyperesthesia. He was readmitted to the hospital on the third day (January 30, 1905) with the following symptoms: Delirium; face flushed; pupils normal, eye-grounds normal; tongue coated; neck rigid; knee-jerks active; Kernig, Babinski, and tâche present; T. 102.2°; P. 110; R. 24. Examination otherwise negative. Urine, normal. Hmg. 80 to 90 per cent., w. b. c., 14,000. C. s. fluid, diploc. meningit. present. For four weeks the same symptoms continued and then gradually disappeared, excepting Kernig's sign, which was of the same type as in the first attack. The temperature became subnormal on the twenty-third day and remained so for several weeks during convalescence. For a week he complained of left abdominal neuralgia, which also affected the leg and foot. Lumbar puncture was performed five times. At the first examination, January 30 (as stated), the diplococcus was found. The same result February 3, March 16 and April 5 were negative. April 9 the diplococcus was absent in the smear but found in the culture. Convalescence was slow, but he made a complete recovery and has remained well since.

Case XII.—William H., U. S., age 13 years, schoolboy. Admitted December 27, 1904. Discharged, improved, January 14, 1905. Two days ago, pains in arms, back, and head; fever; vomiting; restless, talkative, and slight delirium. Next day, retraction of head, occasional strabismus, active delirium, and apparently deaf. On admission, in delirium; face flushed; pupils equal, slightly contracted; no reaction to light; neck rigid and head retracted; bilateral total deafness; scaphoid abdomen; kneejerks present; Kernig well marked on both sides (attempts at passive extension of leg upon thigh results in his shrieking and strong contraction of flexors over thigh). Babinski absent. T. 101°; P. 90; R. 28. Heart, lungs, and other viscera normal. Urine, acid, 1018, trace of albumin, hyaline cases. Blood, hmg., 80 to 90 per cent. W. b. c., 15,000. C. S. fluid, diplococcus meningitidis present. The urine was normal three days later. During the first week, there was a mild degree of optic neuritis which soon subsided. By the thirteenth day, most of the symptoms had disappeared, but the fever continued, reaching 105° on the eighteenth day. He was then taken home at the request of his family, and when seen, December 10, 1905, his gait was slightly ataxic, deafness persisted, but otherwise his health was good. He is now, January, 1906, deaf, but in good health.

Case XIV.—Maurice J., U. S., age 10 years, schoolboy. Admitted, February 27, 1905. Discharged, recovered, May 12, 1905. Three days ago, headache, vomiting, stiffness of neck, and pains in legs. Delirium followed. One brother and a sister were attacked at the same time and all were admitted together. The others died. On admission, well nourished; apathetic; face flushed; pupils and eye-grounds normal; lips dry and fissured; tongue moist and coated; rigidity of neck and lower extremities; knee-jerks normal; Kernig present; Babinski absent; T. 100.8°; P. 100; R. 36. Heart and lungs normal; abdomen distended and tympanitic. Urine normal. Hmg., 80 to 90 per cent.; W. b. c., 21,200. C. s. fluid (15 c.c.), diploc. meningit. present. The course of the disease was acute but mild, the temperature remaining high (103.2°), with slight remissions for four days, and soon becoming normal. After the eighth day, all symptoms abated and recovery was rapid. January, 1906, he was in good health and attending school.

Case XVIII.—William S., U. S., age 11 years, schoolboy. Admitted March 16, 1905. Discharged, recovered, June 9, 1905. Three days ago, headache, vomiting, stiffness of neck, and delirium. On admission, sensorium clear; body well-nourished; herpes labialis; pupils normal; tongue dry and thickly coated; neck rigid; knee-jerks, Achilles, cremasteric and abdominal reflexes exaggerated; plantar diminished, Babinski absent; Kernig present. Thoracic and abdominal organs negative. T. 101.2°; P. 88; R. 24. Urine normal. Hmg. 80 to 90 per cent., w. b. c., 22,200. C.s. fluid (20 c.c.), diploc. not found in smear or culture. The temperature was intermittent, showing daily fluctuations of four to five degrees, the morning remissions touching normal, the evening rise reaching 103° to 104°. This continued four weeks when it became normal. During the first two weeks, in addition to the symptoms enumerated, there occurred retraction of the head; Babinski sign; rigidity of the lower extremities; feeble, rapid, and irregular pulse, and extreme emaciation. Eye-grounds normal. Simultaneous with the fall in temperature in the fourth week, there was an abatement of all symptoms, excepting Kernig and Babinski sign, and rigidity of the lower extremities which persisted during the seventh week, Kernig's sign being the last to disappear. Convalescence was protracted, but he ultimately made a complete recovery. During the course of the disease, lumbar puncture was done four times, the diplococcus being absent at the first examination, but present on March 23 and April 13. The urine was always normal. In January, 1906, he was in good health and attending school.

Case XXI.—Jacob L., Russia, age 10 years, schoolboy. Admitted April 2, 1905. Discharged, recovered, June 9, 1905. Two days ago, chill followed by convulsions; temperature 102°; pain in head and neck; frequent vomiting; delirium, and photophobia. On admission, well nourished, pale and apathetic; general hyperesthesia; pupils equally dilated, reaction normal, ocular fundi normal; tongue coated and moist; herpes labialis; neck and back rigid; extremities cyanotic. Thoracic and abdominal organs normal; pulse and respiration irregular. T. 101.2; P. 100; R. 28. Knee-jerks absent; Kernig present; plantar, cremasteric, and abdominal reflexes exaggerated. Urine negative. Hg. 80 to 90 per cent., w. b. c., 18,400. C. s. fluid (15 c. c.), diploc. meningit. present. The symptoms were not influenced by the temperature fluctuations (from 99 to 103.8°). After the ninth day, all of the meningeal signs disappeared, save rigidity of the neck and Kernig's sign, which persisted until the fall of temperature on the twenty-second day. Convalescence was protracted, but he made a complete recovery. In January 1906, he was in perfect health and attending school.

Case XXII.—Robert L., U. S., age, 5 years. Admitted April 5, 1905. Discharged, recovered, August 3, 1905. Four weeks ago, vomiting and convulsions, followed by rigidity of the neck and stupor.

During the last week, pain in neck and back. Has lost in weight and strength. On admission apathetic; general hyperesthesia; head retracted, neck and spine rigid; pupils dilated, left > right, slow reaction to light, ocular fundi normal; remains of herpetic eruption on lower lip; tongue dry and coated; hearing normal. Thoracic and abdominal viscera normal. T. 102.2°; P. 120; R. 36. Knee-jerks feeble; Kernig present; plantar, cremasteric and abdominal reflexes active; muscular twitching in all extremities; involuntary discharge of urine and feces. Urine normal. Hmg. 80 to 90 per cent. W. b. c., 19,600. C. s. fluid (25 c. c.). Meningococci absent in smear; no culture made. For nearly six weeks he remained in about the same condition, occasionally being delirious, restless and noisy, the morning and evening temperature being from 99 to 103°. At times he became bright and talkative. At the end of the first week (April 12), c. s. fluid (30 c.c., meningococci absent in smear and culture. On the 41st day, there was a sudden rise in temperature to 105°; P. 130; R. 30; with exacerbation of all symptoms, which subsided in a few days. Occasionally he would have a prolonged chill, followed by fever and vomiting. He became very much emaciated and was always apathetic, and most of the time the neck and all extremities were rigid, and there was loss of bladder and rectal control. On the forty-seventh day (April 27) the diploc. meningit. were found in a smear from the fresh fluid. Frequently, during the further course of the disease, the upper extremities were completely relaxed while the lower extremities were rigid in extension. On May 19 (seventy-second day), examination of cerebrospinal fluid negative. Improvement was very slow, but gradually all symptoms subsided, and he was discharged completely recovered. In January, 1906, he was in good health and attending school.

Case XXIII.—Lillian S., U. S., age 15, clerk. Admitted April 7, 1905. Discharged, recovered, May 7, 1905. Three days ago, chill, fever, headache, pain in neck, back, and limbs, and repeated vomiting. Slight hebetude, but sensorium has been clear. Temperature ranged from 99° to 102°. On admission, large well-nourished girl; face flushed; sensorium clear, occasional convergent strabismus, pupils dilated r. > l., reaction normal, ocular fundi normal; hearing normal; tongue moist and slightly coated; rigidity of neck; both knee-jerks active; Kernig present; plantar reflex exaggerated; no Babinski. Heart, lungs, and abdominal organs normal. T. 102°; P. 110; R. 30. Urine, acid, sp. gr. 1025, albumin one per cent. by volume, no casts. Blood, Hmg. 80 to 90 per cent., leucocytosis, 24,400. Cerebrospinal fluid (25 c.c.) diploc. meningit. present. The following day she began to menstruate and continued four days. On the sixth day, chill, T. 104°; P. 142; R. 46; marked apathy, opisthotonus and retraction of head; eyes normal; herpes on upper and lower lips; petechiæ over arms and forearms; but more at elbows, also over buttocks, slightly on thighs, but more marked about knees and legs; slight epistaxis. These symptoms continued with mild delirium until the thirteenth day, when the temperature became normal and convalescence began. The urine was normal at the end of the first week. She made an uninterrupted and complete recovery.

Case XXVII.—William D., U. S., age 15. Admitted May 8, 1905. Discharged, recovered, August 27, 1905. Three days ago, headache, fever, and vomiting, followed by delirium and coma. On admission, semi-comatose; face pale; body well-nourished; general hyperesthesia; pupils equally dilated and react slowly to light, ocular fundi normal; tongue dry and coated; sordes over teeth; general muscular rigidity; opisthotonus and retraction of head with rigidity of neck; knee-jerks and plantar reflexes normal; Kernig well-marked; tâche present; loss of control of bladder and rectum. Heart and lungs normal; abdomen rigid and distended. T. 101°; P. 118; R. 28. Urine normal. Blood, Hmg., 80 to 90 per cent., w. b. c., 15,800. C. s. fluid (20 c.c.), diploc. meningit. present. On the tenth day deafness affecting both sides, but complete on the right. Eight days later, slight right optic neuritis and left irido-cyclitis. All of the symptoms above described continued with a slight fluctuation for two months, the temperature during the first three weeks ranging between 100° and 103°. Dysphagia was occasionally present, and there was frequent noisy delirium and progressive emaciation. The hearing improved but remained subnormal. The right eye recovered, but the irido-cyclitis continued, and by August 9 posterior synechiæ and vitreous opacities resulted and the pupil was contracted and distorted. The tension of the globe was diminished and vision equaled fingers at one foot. Lumbar puncture was performed four times, and the diplococcus was usually found. At one time, the fluid was thick and purulent, and at another no fluid could be obtained although five punctures were made at different levels. General improvement was slow, and when discharged, although he had gained in weight and strength, his gait remained unsteady for several months. January, 1906. General health good. Static ataxia (falls when eyes are closed). Spastic and titubating gait. *Lower extremities.*—No atrophy; muscular power and resistance good on right side; adductor spasm slight on both sides, but more on left. Left, paresis of iliopsoas and posterior thigh group; foot-drop with commencing contracture; and spontaneous dorsal flexion of great toe. Both knee-jerks exaggerated; left ankle-clonus and Babinski; pseudoclonus and slight Babinski right; Kernig absent; Achilles reflex, R. + L. +, cremasteric, feeble; abdominal reflex absent; no objective sensory disturbance. Upper extremities and face normal. Left eye, perception of light; right eye normal. Ears (report by Dr. P. D. Kerrison). Deafness on right side, due to lesion of auditory nerve; hearing normal on left side.

Case XXX.—Roman W., U. S., age 7 years; schoolboy. Admitted June 22, 1905. Discharged, recovered, August 10, 1905. Four days ago headache, followed by chills and fever, pain in neck, and vomiting. On admission, stuporous; rigidity of neck and spine, with retraction of head; pupils equally contracted, reaction to light normal, ocular fundi normal; general hyperesthesia; tongue coated and moist; herpes labialis. Thoracic and abdominal organs normal. T. 102.6°; P. 90; R. 32. Knee-jerks absent; plantar reflex normal; Kernig well marked. Urine, 1010, acid, no albumin, a few hyaline and granular casts. Hmg., 80 to 90 per cent., W. b. c., 19,600. C. s. fluid, diplococcus meningitidis present. A few days later the urine was normal, and within three weeks all symptoms gradually disappeared and complete recovery followed. The temperature during the first week ranged from 99 to 102.6°.

FATAL CASES.

Case I.—Henry S., U. S., age 4½ years. Admitted April 2, 1904. Died May 10, 1904. Seven days ago chill, fever, headache, pains in legs and back, vomiting, and retraction of head. Next day delirium, stupor, involuntary urination and defecation. In same condition on admission, with marked prostration. T. 103°; P. 124; R. 28. Thoracic and ab-

dominal viscera normal. Knee-jerks absent; Kernig and Babinski present. Urine normal. Hmg., 80 per cent. Leucocytosis, 36,000. C. s. fluid (18 c.c.), diplococcus meningitidis present. The temperature fluctuated between 99 and 104°, but remained subnormal after the third week, and the general condition was unchanged. The child was taken home and died of exhaustion two days later.

Case III.—Mary D., U. S., age 14; schoolgirl. Admitted May 2, 1904. Died July 5, 1904. One brother died of cerebrospinal meningitis seven years ago. Mother and uncles died of tuberculosis. Four days ago headache, fever, and vomiting for twenty-four hours. This was soon followed by rigidity of the neck and lower extremities, restlessness, and delirium. On admission, general nutrition good; face pale; left facial paralysis, with slight lagophthalmos; pupils and ocular fundi normal. T. 102°; P. 102; R. 36; heart, lungs, and abdominal viscera normal; rigidity of neck and lower extremities; knee-jerks absent; Kernig present. Urine normal. Blood, Hmg., 90 per cent., W. b. c., 20,000. C. s. fluid (15 c.c.), thick, yellow, and fibrinous; diplococcus meningitidis present. Three days later there was bilateral deafness (hearing returned on the left side). Bronchopneumonia developed during the second week, but gradually subsided. She remained delirious most of the time, with incontinence of urine and feces. Emaciation was rapid and extreme, so that in the course of a few weeks the skin ulcerated over both iliac spines, and bed sores formed over the sacrum, buttocks, and malleoli. Prostration was always pronounced. Acute exacerbations and sudden remissions of temperature were frequent, ranging from 98½ to 102 or 104°. In the third week left keratitis developed and rapidly progressed to ulceration, perforation, and destruction of the eye. The right eye remained normal. All of the meningeal symptoms as at first described continued throughout the course of the disease. She died from exhaustion on the sixty-seventh day.

Case VI.—Adolph S., U. S., 11 years of age; schoolboy. Admitted June 17, 1904. Died June 23, 1904. Ten days ago he began to complain of diplopia and severe frontal headache. Vomited once. Frequent mild epistaxis; anorexia and general weakness. No disturbance of consciousness. No convulsions or rigidity. On admission he was in a stuporous condition, with a blank, expressionless face. He was easily aroused, slowly answered questions, and yawned frequently, then relapsed into stupor. At times he recognized familiar objects and named them correctly. T. 99°; P. 52; R. 18. No rigidity of neck; flaccidity of entire muscular system; pupils equal, normal in size, no reaction to light, ocular fundi normal; knee-jerks, Achilles reflex, and Kernig absent; Babinski present on both sides; cremasteric and abdominal reflex present on both sides; tâche well marked. Heart, lungs, and abdominal organs showed nothing abnormal. Urine, acid; 1010; albumin, trace; glucose, trace; urea normal; microscopically negative. Blood, hmg. 90 per cent., R. b. c., 4,750,000; W. b. c., 12,200. C. s. fluid (15 c.c.), diplococcus meningitidis present in smear and culture. No tubercle bacilli present. Shortly after admission he had several attacks of generalized tremors, but no convulsive movements. Later the urine was passed involuntarily. His condition remained unchanged, and he died from exhaustion six days after admission, on the sixteenth day of the disease. The rectal temperature ranged from 99° to 96.6°; pulse from 64 to 44; respiration from 20 to 16. No autopsy.

Case VII.—Abraham F., U. S., age 7 years, schoolboy. Admitted July 29, 1904. Died April 20, 1905. Six weeks ago, suddenly attacked with general convulsions; stupor and opisthotonus for eight days. Temperature 105°. All symptoms gradually diminished in severity. On admission he looked anemic and was slightly emaciated. Sensorium clear; pupils dilated, equal, reaction normal; ocular fundi normal; slight right internal strabismus; tongue coated and tremulous; neck rigid; tâche present; T. 102.8°; P. 140; R. 28. Thoracic and abdominal organs normal; knee-jerks active; Kernig present; Babinski absent. Urine normal. No blood examination. C. s. fluid, diploc. meningit. present. Irregular temperature persisted for several months, being remittent the first six weeks and later intermittent in type, with periods of normal temperature for five or six days. The meningeal symptoms soon disappeared, and he gained slowly in weight and strength. He was discharged from the hospital in a fair condition, being able to walk, and having had no fever for three weeks. He returned one month later, with a sudden rise of temperature, to 103°, accompanied by delirium and rigidity of the neck, all of which subsided in twenty-four hours. He was perfectly well for a week, when another similar attack occurred, and subsided as before. Otherwise, he seemed to be improving, and was gaining slowly. These attacks recurred, however, for four successive weeks. During the fourth attack he developed measles, and was transferred to the "Hospital for Contagious Diseases," where he passed through a severe attack of measles complicated by bronchopneumonia. He was then taken home, remaining for one month, and was readmitted to the hospital (February 13, 1905), with the symptoms of chronic meningitis and internal hydrocephalus; general emaciation; rigidity of the neck, opisthotonus; rapid irregular breathing; scaphoid abdomen; rigidly flexed upper and lower extremities; involuntary evacuation of bladder and rectum; frequent active delirium with intervals in which he as bright and rational. Emaciation became extreme, bedsores formed, and on the three hundred and seventh day he died of exhaustion. No autopsy. During the attacks of delirium and stupor, cerebrospinal fluid was withdrawn, which resulted invariably in relief of these symptoms for several days. Four weeks before death meningococci were found in the fluid, and the blood examination showed hmg. 80 per cent., W. b. c., 11,600. The urine was always normal.

Case XIII.—Florence J., age 16 months. Admitted February 27, 1905, died April 6, 1905. Two days ago, very irritable and hyperesthetic; slight rigidity of the neck, and the extremities twitched occasionally. On admission, pupils equal, reaction normal, convergence of both eyes; constant grinding of teeth; lips dry; tongue coated and moist; mild bronchitis and irregular respiration and heart's action. T. 102°; P. 130; R. 40. Rigidity of neck and abdomen; knee-jerks exaggerated; Kernig and Babinski present. Urine normal. Hmg., 80 per cent., W. b. c. 18,000. C.s. fluid, diploc. meningit. present. The symptoms continued unchanged during the first three weeks, the temperature ranging from 99° to 104°. The meningeal symptoms then became intensified, emaciation progressed rapidly, and right suppurative otitis developed. Later, she became comatose with rapid noisy respiration, feeble, irregular pulse; conjugate deviation of the eyes to the right side; pupils dilated and irresponsive to light; marked dilation of veins of head and face; intense rigidity of the neck and opisthotonus; extremities rigidly extended, and a purpuric eruption over the

left side of the body. General clonic convulsions for twenty-four hours before death. Lumbar puncture was done four times without relief.

Case XV.—Daniel J., U. S., age 8 years, schoolboy. Admitted February 27, 1905, died March 7, 1905. One brother and sister with c. s. m. were admitted with patient. Two days ago, headache, vomiting, pains in lower extremities, fever, squinting, and delirium followed by stupor. On admission, delirium; semicomatose; high fever; pupils normal; rigidity of neck; knee-jerks and Babinski absent; Kernig present. Thoracic and abdominal organs normal. Urine normal. Leucocytosis. C. s. fluid, thick, fibrinous, and purulent, diploc. meningit. present. All symptoms became rapidly worse, and profound coma supervened. Several lumbar punctures failed to obtain any fluid. Death from exhaustion on the eleventh day. Temperature chart lost.

Case XVI.—George G., U. S., aged 20 years; telegraph operator. Admitted March 7, 1905; died April 17, 1905. Two days ago sore throat, soon followed by severe headache, vomiting, backache, rigidity and tenderness of the neck, photophobia and diplopia. In the evening he became violently delirious. On admission, well nourished; active noisy delirium; pupils dilated, equal; reaction normal; paralysis of right external rectus; frequent twitching of facial muscles; lips swollen; tongue moist, coated, and tremulous; heart and lungs normal; abdomen rigid and tender; loss of rectal and vesical control; rigidity of the neck and opisthotonus; knee-jerks feeble; Kernig well marked; Babinski absent; tâche present. T. 102°; P. 90; R. 30. Urine normal. Hmg., 80 per cent.; W. b. c., 24,000. C. s. fluid, diploc. meningit. present. At the end of the first week deafness developed on the right side. During the next few weeks the temperature was remittent (from 99 to 103°), reaching normal twice during that period, when there was a corresponding amelioration of all symptoms. But Kernig's sign and the absence of knee-jerks persisted, together with marked prostration and progressive emaciation. In the third week a petechial eruption appeared about both knees, and later all of the acute meningeal symptoms reappeared with sudden exacerbations of temperature to 103°, and equally rapid decline, with periods of normal temperature of four to six days. At the beginning of the sixth week he passed into a typhoid state with delirium and stupor, rapid feeble pulse, rapid respiration and cyanosis, extreme rigidity of the neck and extremities, and involuntary urination and defecation. Death from exhaustion. The urine was always normal. Lumbar puncture was performed five times, and from 30 to 40 c.c. withdrawn, with temporary relief. Meningococci were found in every specimen.

Case XVII.—Harry K., U. S., age 16 years; salesman. Admitted March 8, 1905. Died March 31, 1905. Ten days ago chill, followed by headache, fever, and repeated vomiting. Next day rigidity of the neck, delirium, hyperesthesia, and loss of control of bladder and rectum. On admission, delirium and prostration; general hyperesthesia; frequent twitching of fingers and hands; neck rigid and extreme opisthotonus; involuntary urination and defecation. Both pupils dilated, l. > r., reaction normal, slight hyperemia of optic papillæ. Herpes labialis; tongue dry and fissured; sordes on teeth and gums; mouth full of mucous and saliva. T. 103°; P. 118; R. 32. Heart and lungs normal. Abdomen rigid, tender, and tympanitic. Bed sores over both buttocks, right shoulder, and elbow. Tâche well marked; knee-jerks exaggerated; Kernig present; Babinski absent. Urine normal. Hmg., 80 per cent., W. b. c., 22,000. C. s. fluid, diploc. meningit. absent in smear and culture. Five days later meningococci present in c. s. fluid. The above-mentioned symptoms became more pronounced, the temperature ranging from 99 to 102.5°, with increasing emaciation and prostration. Death from exhaustion on the thirty-fourth day. Lumbar puncture three times; meningococci found in last two specimens. Urine was always normal.

Case XIX.—Paul T., U. S., age 16; clerk. Admitted March 30, 1905. Died April 2, 1905. In good health until yesterday, then had sudden chill, severe headache, pain in back and extremities, repeated vomiting, followed in a few hours by delirium and coma. On admission, semicomatose; moaning constantly; involuntary micturition and defecation; face flushed; neck rigid, and general muscular rigidity; bilateral exophthalmos and intense conjunctival injection; paralysis of left external rectus; pupils widely dilated and rigid; ocular fundi normal; no increase of intraocular tension; tongue coated and moist; driveling; dysphagia; heart, lungs, and abdominal viscera showed nothing abnormal. T. 101; P. 88; R. 24. Both knee-jerks exaggerated; Kernig well marked; Babinski absent; plantar, cremasteric, and abdominal reflexes feeble. Urine, sp.g. 1030, contained a small amount of albumin; otherwise negative. Blood not examined. C. s. fluid (30 c.c.) under very high pressure; diploc. meningit. present. He remained in the same condition, with a rise of temperature to 104.8°, and died from exhaustion on the fifth day.

Case XX.—Mamie S., U. S., age 6 years. Admitted March 31, 1905. Died April 10, 1905. Previous history lost. Attack began seven days ago. On admission, stuporous; bilateral exophthalmos more marked on the left side; increased intraocular tension (T 2); partial ptosis on both sides; pupils widely dilated; very feeble reaction to light; ocular fundi normal. Left facial paralysis (lower branches) with loss of faradic irritability. Tongue clean and moist; neck rigid, head retracted; upper extremities flaccid, lower extremities rigid in extension; scaphoid abdomen; knee-jerks absent; plantar reflex R. absent, L. normal; Kernig present. Involuntary urination. Heart, lungs, and abdominal organs normal. T. 101.8; P. 96; R. 28. Urine negative. Blood, hmg., 80 to 90 per cent., W. b. c., 18,000. C.s. fluid (15 c.c.), diploc. meningit. present. The symptoms became more pronounced. There were irregular exacerbations of temperature (from 97 to 102°), complete paralysis of the left third nerve, and increased exophthalmos. The upper extremities remained relaxed, while the lower were in rigid extension, with frequent clonic spasm. She died from exhaustion on the seventeenth day. Lumbar puncture was performed twice. Lysol sol. 2 per cent. 8.5 c.c. was injected into spinal canal without benefit.

Case XXIV.—Arnold M., United States, age 18 months. Admitted April 15, 1905. Died May 22, 1905. Three days ago he became listless and irritable, with fever, and had two general convulsions within three hours. On admission, well nourished; very irritable; general hyperesthesia; pupils equal, reaction normal, convergence of both eyes; thoracic and abdominal organs normal. T. 100.8°; P. 120; R. 48. Slight rigidity of the neck; knee-jerks and Kernig absent; Babinski present (normal in infant). Urine normal. Hmg., 80 to 90 per cent., W. b. c., 14,000. C. s. fluid (30 c.c.), diploc. meningit. present. The temperature continued of a remittent type, showing fluctuations of three degrees daily (from 100 to 103°). He got progressively worse, and at the end of the third week was in a semicomatose condition. There was pronounced rigidity of the

neck with retraction of the head, and tenderness on pressure over the neck and occiput. The pupils failed to react to light, and there was complete immobility of the right eye, and right facial paralysis. Ocular fundi normal. This was accompanied by rigidity of all extremities, exaggerated knee-jerks and plantar reflex, rapid feeble pulse, and extreme emaciation. Ten days before death bronchopneumonia developed, and was soon followed by pulmonary edema, which was the immediate cause of death on the fortieth day of the disease. Lumbar puncture was done four times and from 25 to 30 c.c. withdrawn. Meningococci were found in every specimen.

Case XXV.—Gabrielle M., Algeria, age 20 years, single; clerk. Admitted April 19, 1905. Died April 23, 1905. Eight days ago chill, headache, vomiting, fever, and pain in the abdomen. Five days later rigidity of the neck, soon followed by delirium and coma. On admission, comatose; general nutrition good; face pale; opisthotonus and rigidity of the neck with retraction of the head; bilateral exophthalmos, more marked on the left side; left ptosis, intense conjunctival injection, pupils widely dilated and rigid; no ophthalmoscopic examination. Dysphagia; upper extremities flaccid, lower extremities rigid in extension; abdominal muscles rigid; involuntary urination; knee-jerks exaggerated; pseudoclonus; Kernig and Babinski present. Coarse moist râles over entire chest; abdominal organs normal. T. 101°; P. 70; R. 24. Urine negative. Leucocytosis, 30,000, hmg., 80 to 90 per cent. C. s. fluid, diploc. meningit. present. A few days after admission she began to menstruate. The above described symptoms persisted, with increasing dysphagia, and rise of temperature to 104°. Pulmonary edema developed, and death took place on the twelfth day of the disease.

Case XXVI.—Minnie S., Russia, age 8 years; schoolgirl. Admitted April 27, 1905. Died May 1, 1905. Eleven days ago chill, fever, and general convulsion. Delirious for twenty-four hours. Then had severe headache, pain in the neck and abdomen, and retraction of the head. Symptoms subsided for four days and then returned with increased intensity. On admission, well nourished; face pale; semicomatose; general hyperesthesia; slight rigidity of the neck; tâche present; eyes kept closed from spasm of orbiculares (due to photophobia); both eyeballs divergent, conjunctival hyperemia, pupils equal and contracted, no reaction to light. No ophthalmoscopic examination. Nasal discharge (contained diplococci). Tongue dry and coated; heart, lungs, liver, and spleen normal; abdomen tense and distended. T. 103°; P. 126; R. 38. Knee-jerks feeble; Kernig and Babinski present. Urine negative. Blood not examined. C. s. fluid (30 c.c.), diplococcus meningitidis present in abundance. She rapidly became worse, and two days after admission was semicomatose, with pulmonary edema, clonic spasms of the right upper extremity, pronounced bilateral exophthalmos, dilated rigid pupils, and ptosis of right eye. Upper extremities flaccid, lower, in extensor rigidity; knee-jerks absent; Kernig's sign well marked. (In obtaining this symptom, spontaneous dorsal flexion of the great toe, and also of the other toes, was produced.) Loss of control of bladder and rectum, and gradual rise of temperature to 105°. She died of pulmonary edema on the fifteenth day of the disease, and five days after admission to the hospital.

Case XXVIII.—Charles W., U. S., age 2 years and 2 months. Admitted May 11, 1905. Died June 20, 1905. Three days ago convulsions, vomiting, restlessness, high fever, and slight cough. On admission, well nourished; expression dull; general hyperesthesia; pupils contracted, equal, reaction normal; tongue dry and coated. T. 100°; P. 140; R. 36. Heart's action rapid and feeble, pulse irregular; lungs normal; abdomen distended and tympanitic; rigidity of the neck; knee-jerks and Kernig absent; plantar reflex active; tâche marked. Urine normal. Blood not examined. C. s. fluid, diplococcus meningitidis present. Five days later herpes labialis; ptosis of the left eye; and petechial rash about the neck, soon followed by marked rigidity of the neck and retraction of the head, inequality of the pupils, presence of Kernig's sign, and progressive emaciation. The temperature began to fluctuate, varying from 98° to 105° within twenty-four hours. This condition continued unchanged, and at the end of the fifth week the child was taken home by his mother, and died three days later from exhaustion. Lumbar puncture was done four times without relief of symptoms. The fluid always contained diplococcus meningitidis.

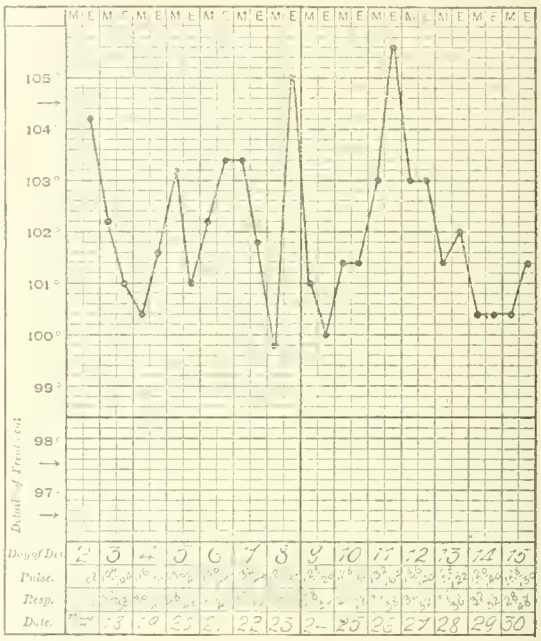

Chart 4.—Case XXIX.

Case XXIX.—Bertha F., U. S., age 6 years. Admitted May 17, 1905. Died May 31, 1905. In good health until last night, when she suddenly complained of severe headache and pain in the back of the neck; had high fever and delirium. This morning vomited several times, and became unconscious. On admission, well nourished; face flushed; comatose; conjunctivæ congested, persistent conjugate deviation of the eyes to the right and downward, pupils dilated equally, slow reaction to light, ocular fundi normal; tongue moist and clean; no herpes; no rigidity of the neck, but child evinces pain when head is flexed; general hyperesthesia; tâche present; knee-jerks and plantar reflex exaggerated; Kernig and Babinski absent; heart rapid and irregular, respirations very rapid; liver and spleen normal. T. 104°; P. 108; R. 76. Urine, 1025, glucose present. Hmg., 90 to 100 per cent., W. b. c., 17,000. C. s. fluid (15 c.c.), diplococcus meningitidis present. The temperature became irregular and remittent, reaching 105.6°. She rapidly became worse, with delirium, stupor, and loss of control of bladder and rectum; clonic spasms of lower extremities, and later clonic general convulsions, ptosis of left eye. Conjugate deviation continued, with paralysis of left

external rectus, right facial paralysis (and loss of faradic response). Rigidity of the neck was never present. Death from exhaustion on the fifteenth day of the disease.

Analysis of Special Symptoms.—The following will be here mentioned: Herpetic and petechial eruptions; muscular rigidity; loss of control of the bladder and rectum; the condition of the knee-jerks; Kernig's sign; the Babinski plantar reflex; facial paralysis; deafness; and eye symptoms.

Herpes and Petechiæ.—The presence of herpetic or petechial eruption seemed to have no particular influence in the prognosis. At least it could not be looked upon as being of unfavorable significance, although the herpes is due to inflammatory lesions in the corresponding ganglia of the fifth nerve, or of the posterior roots of the cervical nerves. In eight of the recovered cases (5, 8, 9, 18, 21, 22, 23, 30) herpes was present, three being associated with a petechial eruption (8, 9, 23). In two cases (4, 10) petechiæ were present alone. In three of the fatal cases a petechial eruption was present in one (16), herpes in another (17), and both herpes and petechiæ in the third (28).

Muscular Rigidity.—Rigidity of the neck was present in twenty-eight and absent in two (fatal cases 6, 29). General rigidity with opisthotonus occurred in three recoveries (4, 22, 29) and in one fatal case (19). A peculiar feature in five cases, three fatal (20, 25, 26) and two recovered (22, 23), was extreme extensor rigidity of both lower extremities, while the upper extremities remained flaccid. I was inclined to attribute this to irritation of the anterior nerve roots in the dorso-lumbar cord.

Bladder and Rectum.—The loss of bladder and rectal control was evidently not occasioned by the spinal meningitis *per se*, but was entirely due to the condition of the sensorium. It occurred only in the presence of delirium or stupor. During the intervals in which the mind was clear, the bladder and rectal functions were normal, and, during convalescence, restitution of function was complete and permanent in every case.

Knee-jerks.—The knee-jerks were absent in fourteen cases, seven (1, 3, 6, 20, 24, 15, 28) fatal and seven (2, 5, 8, 11, 21, 23, 30) recovered. In those who recovered, the knee-jerks returned during convalescence and became slightly exaggerated. In at least six of these cases the knee-jerks did not return after the withdrawal of cerebrospinal fluid, several examinations being made immediately after lumbar puncture and during the following twenty-four hours. I was led to make these observations through a statement made at the last meeting of the American Neurological Association, that when the knee-jerks were absent in cases of cerebellar tumor, they returned after withdrawal of cerebrospinal fluid, thus showing that this symptom was the result of intracranial pressure.

For many years I have noted the condition of the knee-jerks in all cases of acute meningitis, both in children and adults. In the early period of the disease they have usually been absent, to gradually return and become exaggerated, particularly if intracranial pressure symptoms supervened.

Kernig's Sign.—Kernig's sign was present in twenty-seven cases (in twelve fatal cases, and in fifteen who recovered). In three of the fatal cases it was absent (6, 24, 29). In two of these (6, 29) there was no rigidity of the neck; in the other (24) it was very slight. This objective symptom, which is supposed to be essential to a correct diagnosis of meningitis, is, in my opinion, usually the result of the patient's resistance to extension of the leg upon the thigh, in order to avoid painful stretching of the sciatic nerve or the spinal roots which are involved in the exudative process. From numerous observations I have reached this conclusion, for, in many of these cases (excluding the element of general hyperesthesia or arthritis) attempt to elicit this symptom, even while the patient was semicomatose, frequently resulted in expressions of exquisite pain, and often patients would become apprehensive at subsequent visits and beg to have such examination omitted. In several cases tenderness was present over the sciatic foramen and in the course of the nerve trunk in the thigh.

This explanation of the mechanism of Kernig's sign has also been given by Hassan of Chicago (MEDICAL RECORD, September 9, 1905), and it is quite plausible, when we consider that pathologists have demonstrated that all cases of meningitis are more or less cerebrospinal.

The Babinski plantar reflex was present in ten cases. (In infants this is not pathological.) In several patients attempts to elicit Kernig's sign resulted in well-marked dorsi-flexion of the great toe, and in milder degree of the other toes, on the same side. This phenomenon is somewhat similar to the dorsi-flexion of the foot occurring when the thigh is flexed on the abdomen in hemiplegics with secondary degeneration of the pyramidal tracts.

Facial Paralysis.—Facial paralysis was present in four of the fatal cases (3, 20, 24, 29). In one (3) there was slight lagophthalmos. In the others only the lower branches were evidently involved, the orbicularis palpebrarum escaping. This condition is of unusual interest, inasmuch as the faradic irritability was completely lost in the facial nerve and affected muscles. (No electrical examination was made in Case 3.) This was repeatedly demonstrated, and we must assume that the paralysis was the result of pressure upon the nerve trunk from exudation at the base.

In Case 20 the lagophthalmos may have been neutralized by the partial ptosis on the same side, which soon advanced to complete third nerve paralysis. In Case 24 the right facial paralysis was associated with complete right ophthalmoplegia. In Case 29, however, there was right facial paralysis and left ptosis.

Deafness.—The auditory nerve became involved in five cases (recovered, 4, 12, 27; fatal, 3, 16): Case 4. On the fifteenth day, left earache and deafness, permanent; Case 12. On the first day, bilateral, complete and permanent deafness; Case 27. On the tenth day, bilateral deafness, complete and permanent on right; left, recovered; Case 3. On the seventh day, bilateral deafness; recovered in left, permanent right; Case 16. On the seventh day, deafness right.

The permanent deafness was no doubt due to infiltration and destruction of the auditory nerve, as has been demonstrated at autopsy in published cases.

Eye-symptoms.—Eye-symptoms were present in twelve of the fatal cases (3, 6, 7, 13, 16, 17, 19, 20, 24, 25, 26, 29) and in four of the patients who recovered (4, 9, 10, 27). Ophthalmoscopic examination was made once or several times in twenty cases. For obvious reasons it was omitted in the others. In two (17, 27) slight optic neuritis was present. In all others the eye-grounds were normal.

The eye-symptoms occurring in those who recovered were: Absence of pupillary light reflex; horizontal and vertical nystagmus; incomplete paralysis of the right third nerve (partial ptosis and divergence); mild optic neuritis. All of these conditions gradually disappeared. In one case (27) irido-

cyclitis and choroiditis developed and terminated in permanent unilateral blindness.

Among the fatal cases: Intense conjunctival hyperemia; dilated pupils with retardation or loss of reaction to light; convergence of both eyes; divergence of both eyes; pronounced bilateral exophthalmos; persistent conjugate deviation to the right and downward; partial or complete third-nerve paralysis; paralysis of external rectus; complete right ophthalmoplegia. In one case (3), during the third week, left keratitis developed, with subsequent ulceration, perforation, and destruction of the eye.

Let me direct your special attention to cases 19, 20, 25, and 26. In all of these fatal cases bilateral exophthalmos was a prominent symptom. In all probability it was due to hyperemia of the retrobulbar orbital tissues. In none of the early or recent reports of epidemic cerebrospinal meningitis have I found this symptom mentioned, and personal inquiry among physicians in this city who have had charge of many cases has failed to elicit information of similar instances. Hence, this symptom must be either quite unusual, or it has escaped observation. The protrusion of the eyeballs was more pronounced than is ordinarily observed in patients with Graves' disease. It was usually accompanied by intense conjunctival hyperemia and widely dilated rigid pupils. In several of these patients the pupils were dilated *ad maximum*, a condition which is never the result of paralysis of the sphincter alone, therefore the extreme dilation must be ascribed to superadded irritation of the sympathetic fibers.

The intraocular tension was increased to T.2 in one case (20); in the others it was apparently normal. In two (19, 20) the eyegrounds were normal. The others were not examined. In one of these cases (20) the exophthalmos was associated with complete oculomotor paralysis on one side. In two others (25, 26) complete ptosis was present on one side, without involvement of other external muscles supplied by the third nerve. In another (19), the left external rectus was paralyzed. It will be noted that the severe eye-symptoms in the fatal cases were in consonance with the other manifestations of the disease. In the four cases just enumerated, all of the patients were comatose or semi-comatose when admitted on the first, seventh, eighth, and eleventh days of the disease, and died on the fifth, eighteenth, twelfth, and sixteenth day respectively. The withdrawal of cerebrospinal fluid proved ineffectual in reducing the exophthalmos. From a careful study of these cases, I would lay great stress on the importance of such eye-symptoms and their grave prognostic significance. In a report of forty cases with special reference to the eye-symptoms, Randolph states (Bulletin Johns Hopkins Hospital, Vol. IV, 32, 1893) "patients with 'enormously' dilated pupils died." Among the 111 cases of cerebrospinal meningitis reported by Councilman, Mallory, and Wright (Mass. State Board of Health Report, 1898, p. 143) "various abnormal conditions of the eyes were noted in sixty-seven cases." They state that no systematic examination of the eyes was made in all cases. In one case "bulging of the eyes was noted." After a review of the literature we must conclude that the eye-symptoms vary with the type of the epidemic and the degree of infection.

Prognosis.—The prognosis in cases of cerebrospinal meningitis is often an extremely perplexing problem, particularly during the early period of the disease. Apparently mild cases may die, while those presenting a serious and alarming aspect have often been known to recover. In infants and young children the mortality is high. Careful observation of the patients whose histories are here recorded, has led me to the conclusion that the following symptoms are of grave significance and indicative of a fatal termination:—exophthalmos and widely dilated rigid pupils; prolonged stupor or coma with slow pulse, subnormal temperature and general muscular flaccidity; persistent coma with high fever and extreme rigidity after the first week.

Treatment.—Good nursing and proper feeding are the most important features in the treatment. When the weather permitted, the patient was kept in the open air the greater part of the day. Several improved more rapidly on a mixed diet during and after the second week. The ice-bag was applied to the head and neck in every case, but in my opinion its utility is doubtful. Hot saline rectal irrigation or hypodermoclysis often proved extremely valuable in improving the vitality. The hot bath at a temperature of 105° for 15 or 20 minutes given several times a day, usually allayed excessive irritability and delirium and temporarily improved the patient's general condition. Whiskey, strychnine, digitalis, etc., were given when indicated.

Morphine was given hypodermatically for the relief of pain, restlessness, and delirium in the earlier cases. In one case vomiting resulted, and recurred after every dose, and it was therefore discontinued.

Ergot was then resorted to, and it not only relieved the pain, restlessness, and delirium, but also improved the condition of the pulse. In all of the succeeding cases, ergot was used as a routine measure with the most gratifying result. In only one or two instances morphine was administered when the patient became uncontrollable. While I consider ergot the most valuable drug in this disease, it must be understood that it is comparatively useless when given by the mouth in the customary way. Hence, the familiar statement of various writers that "ergot proved useless." It was administered in the form of an aseptic solution subcutaneously over the buttocks every three or four hours. No abscesses followed. The preparation used was Squibb's solid extract of ergot (aseptic) one dram, in distilled sterile water one ounce. Children received from 10 to 15 minims, and adults, from 15 to 30 minims at a dose. This was continued in some cases for five or six weeks. In the majority of instances the dosage was gradually diminished and the drug discontinued at the end of the second or third week.

In several acute cases, salicylate of sodium was administered per rectum (a method suggested by Dr. Seibert of this city), but without benefit.

Lumbar Puncture.—Lumbar puncture was performed once or several times in every case, either for diagnostic or therapeutic purposes. It was never followed by unpleasant results. In restless and noisy patients chloroform was used. A Quincke needle was usually employed. (Exhibition of instruments.) After some practice, one can soon decide whether or not the needle has entered the spinal canal without watching for the appearance of fluid. It is the consensus of opinion among those familiar with this procedure, that the number of "dry taps" decreases in proportion to one's skill in the technique, but the fact is now well-established that instances often occur in which fluid cannot be obtained.

On one occasion, when the members of the house-staff doubted that the needle had entered the canal, as no fluid escaped, it was left *in situ*, and another introduced through the lowest lumbar space. Sterile water was then injected through one needle and it promptly flowed out through the other. I have repeatedly observed, that several days after a successful puncture, a "dry tap" may result, if the puncture is made in the same location. This must

be due to the formation of inflammatory adhesions at the site of the previous traumatism. If the needle be inserted in another space, fluid may then be obtained. The diagnosis of this type of cerebrospinal meningitis can usually be made from the clinical phenomena alone. Nevertheless, in doubtful cases lumbar puncture is essential. Even in pronounced cases, the meningococcus may be absent at one examination, but be found at a subsequent puncture. Therefore, when uncertainty in diagnosis still exists, it is unwise to exclude the disease after one negative examination. In some of the cases herein reported, even during the period of exacerbation (when the diplococci are usually present) they have not been found in either the smear or culture. In Case 6, in which there was complete muscular flaccidity and subnormal temperature, a correct diagnosis would have been impossible without examination of the cerebrospinal fluid.

In some of the fatal cases, after several satisfactory punctures had been made in the early period of the disease, subsequent attempts to obtain the fluid often proved unsuccessful.

As a measure for the temporary relief of excessive intracranial pressure, its therapeutic value must be conceded. It has often been disappointing, however, after withdrawing 50 to 60 c.c. (all that could be obtained). Probably in such cases the foramen of Magendie was closed by the inflammatory process. In two of the patients who recovered (2, 9), lysol solution was injected into the spinal canal. In the former, a one per cent. solution was used without apparent effect. In the latter, the solution was of ten per cent. strength, and it seemed to have some influence in hastening recovery. It was also used in several of the fatal cases without benefit. Of course, no satisfactory conclusions can be drawn from these cases. I am indebted to my former house physicians, Drs. Steiner and Barnert, for assistance in preparing the histories and temperature charts.

56 East Fifty-eighth Street.

THE HEART IN TUBERCULOSIS.*

By WOODS HUTCHINSON, A.M., M.D.,
REDLANDS, CALIFORNIA.

Ever since the days of Hippocrates, in our study of the consumptive, we have focused our almost entire attention upon his lungs. This was both natural and rational, and up to a certain point tended to progress. It led to the masterpieces of clinical observation by Laennec and Louis, and finally to the bacteriological triumph of Koch, and with the attainment of this last it did for a time appear that the last word had been said upon the pathology and pathogeny of consumption.

Without the bacillus no tuberculosis; without its localization in the lung no consumption.

It was not long, however, before uneasy suspicions began to raise themselves, that both the lodgment of the bacillus in our tissues and its special preference for the lung as a place of growth, were dependent on other factors entirely outside of both the bacillus and the lung.

From the postmortem room came the evidence, in rapid succession with overwhelming force, that the temporary and local lodgment of the bacilli, not merely in the body, but even in the lung, was the commonest pathological accident to which the species is liable, and occurs at some time during life in a percentage of individuals, which at first was stated at thirty, then rose to sixty, and is now placed at from seventy to eighty.

*Read before the California State Medical Society, Riverside, April 19, 1905.

The presence and even the lodgment of the bacillus in our tissues, though, of course, indispensable, is a relatively secondary factor in the development of consumption. This sent us afield for the discovery either of some particular type and configuration of general bodily structure, or of defect in the lung itself or in some other organ, whose condition made possible the triumph of the bacillus.

We at first sought refuge in vague terms, like "lowering of the general vitality," "depression of the bodily powers of resistance" and "vulnerability" of the tissues, but these, like many other explanations, were soon seen to be mere restatements in graceful and euphonious language of the problem at issue. That a lowering of the vital resistance is an important factor no one doubts for a moment, but it simply raises the questions Of what sort and Why?

Then a futile attempt was made to hark back to the old diathetic delusions so prevalent a couple of generations ago. The classical *habitus phthisicalis* was rejuvenated and brought upon the stage, only, however, to be quickly sent back to the wings. In addition to its vagueness, the conception was found to prove altogether too much. Nearly every authority describes at least two, and sometimes as high as four, different types of complexion, stature, features, etc., which make the possessor thereof specially and peculiarly liable to tuberculosis. For instance, we all recall the famous types, "pretty," and "ugly" struma, the one with clear skin, bright, expressive eyes, aquiline features, abundant, light, wavy hair, tall, slender figure, tapering fingers, and blue veins; the other swarthy, thick-skinned, dark haired with heavy features, squat-built and stupid. The delicate child who could not, by a little judicious exaggeration be made to fit under one of these types would be hard to find, and one is ready to suspect that they are simply another of the innumerable incarnations of the powers of light and darkness, Ormuzd and Ahriman, whose prototypes are still portrayed upon the stage of popular melodrama.

Then there is the color type, the individual with red or tawny hair, clear or freckled skin, and dark eyes, eyebrows, and lashes. This type of individual may contract tuberculosis, of course; but after twenty years of observation and careful inquiry, I have been unable to find any adequate basis for the notion that he does so in larger percentage than other types of complexion, and I suspect the impression to be one of the survivals of the ancient ethnic prejudice against red hair, as exemplified in the cynical Spanish proverb "Trust no man with red hair—and no woman with hair of any color.'

We have also had described a florid and athletic type which is peculiarly subject at adolescence to the attack of this disease. In fact, the more we study these alleged "strumous" and "consumptive" types, the more I think we are driven to two conclusions: First, that almost any undeveloped, languid, or unhealthy child or young adult, from whatever cause defective, could be fitted under one or other of them. Second, that such distinctive features as are present in those who afterward become clearly consumptive are almost invariably the signs of an early stage of tuberculosis, or of tuberculous involvement itself, most frequently probably in the glandular system; but many of them clear signs of beginning involvement of the lung itself, such as rapid pulse, cold extremities, chilliness, easy fatigue, afternoon flush, sparkle of the eye, etc. About all that can be made out of

the bewildering profusion of diathetic types is that children and young adults whose development is defective, or whose general vigor is lowered by any cause, whether hereditary, dietetic, sanitary, or economic, are more liable than the average to develop tuberculosis, which everybody knew beforeh and.

One general physical characteristic may perhaps be said to be proven to be a predisponent to the attack of tuberculosis, and that is unusual tallness of stature. This, of course, applies only to those who have reached somewhere near the maximum height at, say, from sixteen to eighteen years of age and upward; for tallness in children is, in a safe majority of cases, a sign of vigor.

Almost every observer who has paid attention to the point has expressed an unhesitating opinion that men over five feet eleven inches, and women over five feet seven inches in height, are distinctly more subject to the attack of the disease, and succumb to it more rapidly than the average of the race. The data are as yet, however, too incomplete for the drawing of any safe conclusion, inasmuch as it will be necessary to carefully tabulate not only the number of tall individuals developing tuberculosis but the percentage of such individuals in the race under consideration.

An investigation should at the same time be made of the morbidity of those equally undeveloped below the average stature. It may only be found to resolve itself into an instance of the well-known greater liability of extremes to vary and suffer from accidents and casualties, but from a somewhat careful study of the vigor of the giants and dwarfs I should be strongly inclined to the belief that the little people would be found to have far greater resisting power than their tall cousins at the opposite extreme, who are excessively subject to tuberculosis, and whose longevity is only about half that of the dwarfs. The most striking illustration that I have been able to find is that presented by two regiments of the British Army. One of the Life Guards, those great hulking, beribboned, and glittering popinjays who are to be seen astride their coal-black steeds on guard before the Palace gates at Whitehall, and the other the Woolwich Corps of the Royal Artillery. Both these regiments are recruited on precisely the same standards, except that of height, the minimum of which is placed in the Life Guards at six feet—their average being nearly six feet two inches—while in the artillerymen a minimum is allowed lower than that of the rest of the army, namely, five feet four inches. The men are fed and housed in barracks of practically identical sanitary construction, and yet the death rate from tuberculosis in the Life Guard giants is a little more than double that in the artillery dwarfs. Of twenty-two patients in our Portland Camp at one time two of the men were over six feet, and two of the women over five feet seven, a much larger proportion than in the rest of the community. In all giants and very tall men whom I have examined, the heart is relatively undersized.

Our next search was in the direction of some special shape or size of lung, or what is practically identical, chest, as furnishing conditions favorable for the lodgment and propagation of the bacillus. The conclusion to which it has led us is similar to the one upon diathesis, namely, that whatever form of chest is connected with, or indicative of, arrested, backward, or abnormal development of any sort in children and youths, will be found most frequently present in consumptives. This, as nearly seven hundred measurements have now shown, is a round, high-indexed type, its average index being in the neighborhood of 80, as compared with the normal of 70, thus showing the consumptive chest to be ten degrees rounder and deeper than the normal, instead of flatter. But this is neither a specially defective chest mechanically, as far as expansion is concerned, nor even markedly undersized, for what it lacks in breadth it almost makes up in increased length. "Surplus" or unused lung is the site of danger in tuberculosis, whether it be found in an undersized or an oversized chest.

I am coming to have a strong suspicion that the question of respiratory capacity is one of general muscular development, and that the increase which unquestionably comes with gymnastic and athletic training of any sort is to a large extent due to the increased demands upon respiratory capacity made in the course of these exercises, which is again further responded to by the well-known increase in size of the heart and aorta which occurs in athletics. In other words, the boy who is taking gymnastic training, or, for the matter of that, who is developing vigorously and normally, is constantly calling into play more and more of his lung surface, already present, rather than causing any growth of new lung tissue. The ideal use of gymnastic and athletic training and of pulmonary and breathing exercises should be not so much to expand the lungs as to call into vital metabolic play as large a percentage of their area as is reasonably practicable. It is the quiescent, "waste" lung tissue which becomes a culture medium for the tubercle bacillus, and our aim in physical development should be to build up the body and heart symmetrically to the point of utilizing the entire lung area.

As is well known and recognized by all intelligent physical trainers now, muscular training is at bottom a matter of heart development, and all other considerations are secondary to this.

This round chest, is as my measurements first showed, and as the admirable recent paper of Besessen further demonstrates, a persistence of the type of chest normal in the boy of fourteen to sixteen years of age, an arrest in the transition of the chest from the almost perfectly round one of the embryo to the flattened adult form. Like the other physical defects alleged as predisponents to consumption it should probably be regarded as a sign of arrested and imperfect development. This view, I might add, is strengthened by the exceedingly interesting measurements of Evans upon the insane and other defectives in the Cook County Infirmary and of Arthur McGugan upon the chronic insane in the Michigan State Hospital at Kalamazoo, the average chest index of both of these groups of defectives being almost as high as that of the consumptives.

The conclusion to which we are rapidly being driven is that the cause, if discoverable, which turns the scale in favor of the victory of the bacillus in consumption, is to be found outside of the lung. This has led to the study of the conditions of other organs, among them the heart, which being enclosed in the chest and in close contact with the lung and intimately associated with the latter in the process of respiration, has received first, and perhaps the largest, share of attention.

From a very early period of clinical studies suggestions have been made connecting the condition of heart with tuberculosis. The fathers of physical diagnosis, Laennec and Louis, and later Rokitansky and Bizot, were strongly of the opinion that tuberculosis usually occurred in individuals with small hearts. Louis, in 112 autopsies upon tuberculous individuals found the heart enlarged

only three times, but subnormal in size in about half of the cases.*

Beneke in 1878 announced the same conclusion, based upon a large number of clinical examinations and autopsies. Both the fathers of the open-air treatment of tuberculosis, Bodington in England and Brehmer in Germany, were firmly impressed with the same belief, and in fact based their superbly successful treatment upon it, and Walther to-day holds the same view.

Fothergill declared that the typical consumptive was the individual with the small heart and the large lung. Spatz, quoted by Norris, collected data from 327 tuberculosis autopsies in which the relative size of the cardiac orifices, wall, and chambers were recorded. He found the heart in the majority of instances smaller than normal, with a tendency to left ventricular hypertrophy. The aorta was often found subnormal in caliber, especially in women.

Norris also quotes a recent study by Bouchard and Balthazard, who estimated the size of the heart in ninety cases of pulmonary tuberculosis during life by means of the fluoroscope. The results of their investigations showed two classes of consumptives, first, those who had contracted tuberculosis exclusively from exposure to infection, though not predisposed; second, those who were predisposed. In the first class the heart was normal in size; in the second it "possessed only one-half of its natural proportions." In other words, the heart had 0.5 square centimeter less area for every kilogram of normal body weight than would have been the case in the normal individual. Norris in his autopsies at the Phipps Institute found that in a very considerable number of cases of tuberculosis the heart is subnormal in size.

On the other hand, certain observers who have investigated this very point have come to varying or even determinately opposite conclusions, but the names are both fewer in number and less in weight than those already quoted.

Hirsch, for instance, found the heart enlarged in 44 per cent. and abnormally small in only 5 per cent. Renault came to similar conclusions, but both of them called attention to a factor which must be taken into account, and which partially explains this discrepancy. This is the distinct early hypertrophy and later dilatation of the right ventricle, which naturally follows from increased resistance in the pulmonary circulation due to the exudative and destructive lesions of the disease. Other observers have called attention to a slight but distinct tendency to hypertrophy of the left ventricular wall, and all have laid stress upon the readiness with which dilatation of both ventricular cavities may occur.

The ancient doctrine that valvular disease of the heart confers some sort of immunity against pulmonary tuberculosis and is seldom found in the tuberculous, has been pretty completely disposed of. It seems to have rested chiefly upon oversights of observation and conclusions drawn from inadequate masses of statistics. Nearly all recent reports, both clinical and from autopsies, show almost as high a percentage of valvular lesion in the tuberculous as in the rest of the population.

The only dictum which appears to have received confirmation from the later studies points in exactly the opposite direction, namely, that stenosis of the pulmonary orifice distinctly favors the development of consumption and makes its course much more rapid and hopeless when it does appear. This has been clearly shown in no less than three cases under my own observation in the last six months at the Portland Open Air Sanatorium.

My attention was first called to the size of the heart in tuberculosis from the point of view of comparative pathology. I was engaged for nearly two years in making autopsies upon the bodies of the animals dying at the Gardens of the London Zoological Society, in Regents Park, where, of course, I found large amounts and almost infinite variety of tuberculosis and tuberculous lesions. After I had accumulated a sufficient number of cases I began endeavoring to arrange them so as to accord with some biological factor. I, first of all, tested the question of the zoological affinities, but this was quickly found to have no bearing. Higher and lower alike, Bovidæ, Canidæ, Quadrumana, bird and mammal were found subject to the disease. I next investigated the question of food, and here a certain amount of parallelism became apparent. While tuberculosis can be found in both animal and vegetable feeders in captivity, it never becomes a common or frequent cause of death except in herbivora or mixed feeders. While present in the carnivorous Canidæ, Felidæ, Viverridæ, and Mustelidæ, and in the Raptores among birds, it never becomes of more than very low frequency. While it reaches the level of a pestilence in the herbivorous Bovidæ (cattle, etc.), the apes and monkeys in mammals and the Gallinæ (fowls, pheasants and turkeys) among the birds. But there are curious variations among vegetable feeders. For instance, cattle and antelopes are exceedingly subject to the disease, while the equally purely herbivorous, sheep, goats, and deer, as well as horses, zebras, and asses, are almost exempt. Some other factor must be sought, and after a number of false clues I began finally to work along the line of the relative size of the heart in proportion to the body weight; and here the results ranged themselves in parallel lines with surprising uniformity. Not one of the carnivora, either bird or mammal, was found to have a heart much less than one one-hundredth of its body weight while among the herbivora, both bird and mammal, none of these whose heart weight was in excess of this standard, was found to be susceptible, except in very moderate degree. Practically all of those who were susceptible were found to have heart-weights far below this proportion. This explained nearly all the inconsistencies among the different groups. For instance, among birds, the carnivorous eagle, hawk, owl, and vulture, whose heart is about 1-115 of their body weight, suffer from tuberculosis (6 per cent. of all deaths) than the mixed feeding water-fowl with their 1-100 hearts (3 per cent.) and the vegetarian parrots, with a heart 1-80 of their body (1 per cent.). These last show both the largest heart and the lowest tuberculous death rate among birds. Among the grain eaters, the turkey, the fowl, and the pheasant, with hearts of about 1-250 of their body weight are simply riddled with the disease(12 per cent.), which contrasts sharply with the parrot's heart of nearly triple the size and very low susceptibility. In mammals, the carnivora with their large hearts show (except in the case of the dog under conditions of domestication) a very low susceptibility; while among the herbivora the heart line runs absolutely between the sheep, deer, and goats, and the cattle. The deer, with a heart of 1-90 of its body weight is almost absolutely immune, while the antelope, in the same group, with a heart weight of 1-200, is exceedingly susceptible. The cow, with a heart weight of barely 1-250 of its body weight is, as every one knows,

* Quoted by Norris, "Tuberculosis and Heart Disease," *American Journal of the Medical Sciences*, October, 1904.

exceedingly subject to the disease, while the sheep, placed under even more unfavorable and unnatural conditions, with a heart weight of about 1-100, is almost completely immune. The same relation explains the marked immunity of the Equidæ (horse, ass, and zebra), even under domestication, for their hearts range from 1-90 to 1-100 of their body weights.

It is interesting to note in this connection that Brehmer in his investigation of the size of the heart in tuberculosis found that in strong, well-fed, and healthy oxen the heart was larger relatively in proportion to the size of the lungs than in those which were underfed or less robust.

With this apparent parallel in mind I have been carefully observing the cases of tuberculosis which have come under my own observation during the last five years, and have been struck, first, with the remarkable infrequency of cardiac hypertrophy in these cases, a condition in fact, which I have never found except in cases of valvular lesion, or of renal complications, and with the frequency with which the heart would be found to be, by all physical signs, undersized, as well as weak and rapid in its action, with a distinctly defective first sound. In fact I have come to regard the rate and quality of the pulse as the most important and significant single symptom, both in diagnosis and prognosis.

Since opening our Portland Open Air Sanatorium for consumptives in January last, some eighty or ninety cases have come under my observation. In all but fourteen of these, the heart was noted as weak, defective in its first sound, abnormally rapid in its beat, giving a peculiar soft, running, easily compressible quality to the pulse.

Owing to the pressure of work and innumerable calls upon our time connected with the founding and equipment of the rapidly growing institution, which enlarged from three cases early in January to thirty-five early in May, it was not possible to make as careful a study and measurement of many of the cases as might have been desired. The outline of the heart was, however, carefully mapped out, both by deep percussion and by ausculatory percussion in sixteen cases, with the interesting result of finding the average distance of the apex from the midline of the sternum to be 6.5 centimeters instead of the normal 7.5 to 9 centimeters (Vierordt). That this was not due to any displacement of the heart from pleural adhesions, or the pressure of a consolidated lung was clearly shown by the fact that the right border of the heart, instead of extending 4 to 5 centimeters from the midsternal line was found to average barely 3. In other words instead of extending a full finger's breadth to the right of the right border of the sternum it barely reached the latter line.

Of course I am aware that many factors must be taken into consideration in the tuberculous chest, which might render this method of outlining the heart not absolutely dependable. Most of these could, however, be excluded in this group of cases as in all of them the involvements of the lung were limited to the upper third, and did not invade the neighborhood of the heart, or mediastinum, and all were free from any pleuritic adhesions which were discoverable.

In only one of these cases was there any valvular lesion. That these measurements are at least approximately correct is also clinically corroborated by the fact that the three cases in women which showed the apex extending the least distance from the median line, namely 5.3 and 5 centimeters, were also those showing either the most rapid course of the disease or the most uncontrollable forms, while the three lowest among men, namely 6, 6.1, and 6.2, showed similar characteristics, the lowest of all having since died, and the next one being practically unimproved after nearly four months of treatment. The one case which came up to the average, namely 8 centimeters, was far and away the most vigorous individual of the entire series, showing only a limited lesion and making a rapid recovery. The average distance of the apex beat from the midsternal line in the sixteen cases was 6.5 centimeters, as compared with the normal distance (Vierord and Hornkotel) of from 8 to 9 centimeters. The extension of the cardiac dullness to the right of the midsternal line, averaged 2.8 centimeters, as compared with the normal 4 to 4.5 centimeters. While this series is far from large enough to serve as a basis for positive generalizations, it does furnish a distinct "straw" in corroboration of my former belief, based upon general and clinical grounds, that an undersized heart is closely associated with the development of consumption.

It will, of course, be argued, as already by Potain, that a certain amount of this apparent diminution in the size of the heart is due to the general wasting characteristic of the disease. While this possibility must be borne in mind, yet it hardly seems to me to be adequate to account for the degree, for two reasons. First, that both by these measurements, and by the autopsy—findings already referred to—the consumptive heart is from 30 to 40 per cent. less than the normal proportional size, while the total wasting of the body, even in the most extreme cases, does not exceed 15 to 20 per cent. In none of these cases examined did the loss of body weight amount to more than 15 per cent. and in most of them did not exceed 8 or 10 per cent. All were cases in the second or early third stage of the disease, able to be up and about and in fair flesh and strength. Moreover, as the classical experiments of Liebig showed long ago, the heart muscle in starving dogs is, next to the central nervous system, the very last tissue of all to suffer, and loses least weight in proportion. To put it very roughly the diminution in length of the heart in these individuals is from a normal of 12 to 14 centimeters to 8.3 centimeters, a deficiency of nearly 30 per cent., while the loss of body weight is no case exceeded 15 per cent., and averaged only about 8 per cent.

I think, then, that we are justified in regarding the singularly constant and otherwise inexplainable tachycardia of the consumptive as due not merely to the direct effect of the toxins upon the vasomotor center and possibly upon the cardiac ganglia, but also to a weak, inadequate and frequently undersized heart, with imperfect muscular development and a poor first sound. As to the prognostic significance of this cardiac defect, my small group of figures are absolutely in accord with the much larger ones already accumulated by Norris, Hirsch, and West. Hirsch, by the way, attributes the tachycardia to the undersized and imperfectly developed condition of the heart.

Of the thirty-one cases at the sanatorium which have been under observation for three months or more, sixteen presented a pulse of over 105 on admission. Of these sixteen, six are dead; in four the disease has progressed steadily and constantly, three have made moderate improvement, one has made a marked improvement, and in only one has the disease been temporarily arrested. Of the fifteen with a pulse below this level, four have had a complete disappearance of all symptoms and have returned to work, six are gradually improving, three are slightly improved, two are unimproved and

one is dead. The rate of the pulse was in no way parallel with either the stage of the disease or the elevation of the temperature. Some comparatively normal pulses having an afternoon temperature of from 101° to 103°, and a number of pulses of from 105 to 110, having an afternoon temperature of only 98.9° to 99.5°. The five highest cases, having pulses ranging from 134 to 165, were without an exception conspicuous not merely for the serious and rapidly progressive character of the disease (three of them being already dead), but also for the shortness of its duration previous to admission, ranging all the way from six weeks to seven months. On the other hand the five lowest pulse-rates, ranging from one subnormal pulse rate of 50, up to 90, the average being about 80, contained three of the seven recoveries and only one of the failures to improve, and the disease had lasted for periods ranging from seven to eighteen months, previous to admission.

In fine, I think we are justified in now regarding the heart in consumption in much the same light as we already do in pneumonia. In both diseases the seat of the principal and most rapid growth of bacilli and formation of toxins is in the lungs, but death occurs, not from interference with the respiratory area, but from poisoning of the heart ganglia and heart muscle. If in the individual attacked by pulmonary tuberculosis the heart happens to be undersized or imperfectly developed, or its muscle wall of inadequate vigor, or in a condition of malnutrition from insufficient food, confinement or overwork, we have, what I believe to be the most important single condition in the *habitus phthisicalis*. In short, the individual predisposed to tuberculosis is the one with the small, or muscularly inadequate heart and a lung large, or of normal volume. To develop the skeletal muscles, and through them, the heart, up to the level of the lung, should be our aim in prophylaxis. The first sound of the heart should have almost the same prognostic importance and significance as in pneumonia or typhoid fever.

What influence has this view upon our treatment and attempts at prevention? It helps to explain the admirable and excellent results which we had obtained from treatment, which, though originally conceived upon this ground by Bodington and Brehmer, has long since lost sight of this relation.

First of all, the putting of the patient at absolute rest as long as there is an afternoon temperature of 100° or over, is precisely of the same common sense logic which leads us to put our edematous and gasping patient with the big aortic regurgitant murmur to bed and keep him there.

Secondly, the enormous overfeeding with highly nutritious foods containing a large percentage of live proteids, in the shape of eggs and milk, tends both to neutralize the toxins, which are poisoning the cardiac ganglia and breaking down the cells of the muscle-wall, and to supply nourishment in a readily soluble form to make good the defect. Overfeeding is the weightiest part of our modern treatment of consumption.

Thirdly, the constant exposure to the purest and freshest of air gives adequate amount of oxidation with the minimum of depth and frequency of respirations and consequent reduction of the demands on the overtaxed heart. In short, the whole rationale of the open-air treatment looks much more toward the heart than it does toward the lung. The chief value of exposure to the open air is to enable the patient to overfeed.

In the drug treatment of tuberculosis, the keen chemical insight which led Jacobi to rely chiefly upon the prolonged administration of small doses of digitalis from which he has recently reported such excellent results, was based upon the need of improving cardiac nutrition.

Nor is its bearing less direct upon our measures for prevention, from the point of view of the *terrain*, the soil. It emphasizes heavily the value and importance of promoting normal, vigorous development of the entire body and of every organ therein harmoniously. Pulmonary gymnastics, as such, with a view to expand the lungs, are nearly as foolish here, as they are in acute stages of the disease, and our physical educators have now come to fully recognize that muscular development, however symmetrical and striking which does not proportionately build up and react upon the heart, is of little value from the point of view of vigor and resisting power. Your champion athlete is often a very poor life-risk—balance and reserve power, not horsepower, are what count in the long race of life.

I have been very much struck during the past ten or twelve years in my examinations of delicate, backward, and undeveloped children, in noting to what a marked degree the condition of the heart runs parallel, and indeed in some cases exceeds the other symptoms. The apex beat is almost invariably nearer the median line than normal, and in several cases I have found it at the age of 12 or 14 still in the fourth intercostal space. The little patients are often brought in complaining of shortness of breath on exertion, easy fatigue, faintness, persistent rapid and violent beating of the heart, palpitation, and in some cases attacks of what are almost like mild, functional angina. In fact, I have come to look upon a large percentage of these cases of physical backwardness in children as what may be roughly stated as the body being too big for the heart. Any measures which can be adopted to relieve the arrest of development and lowering of nutrition, or the removal of the most common single ailment in my experience —adenoid masses in the nasopharnyx—will be promptly followed by an improvement in the heart condition, which is just as striking as that in the general system. Those in whom adenoids are not present are frequently improved by small doses of either thyroid or suprarenal extract, or the two combined, and in some cases digitalis; and of course nothing is better for these conditions than life in the open air, cold bathing, and abundance of meat in the diet.

In fact the study of the heart in consumption brings us back, as does the study of all other organs, to a condition of arrested or imperfect development. The heart at birth and for the first two or three years of life is slightly but distinctly larger proportionately than in adult life. This relative hypertrophy, however, rapidly disappears, and by the period of puberty has been replaced by a slight divergence in the opposite direction, as the studies of Oppenheimer have shown. If this temporary hypoplasia, or hypotrophy, remains permanent we have precisely the condition which invites the development of pulmonary tuberculosis.

It is no mere coincidence that an arrest of the chest-shape at this same period is also found to be an important predisposing factor in the development of tuberculosis.

My conclusions as a basis for further investigation are:

That a weak, undersized, muscularly deficient heart, indicated by weak, rapid pulse and defective first sound, approaching embryocardia, is one of the most constant and significant conditions present in consumption.

That this condition in a considerable percentage of cases precedes the development of tuberculosis; the earlier in the disease this condition is presented, and the more striking its degree, the more serious the prognosis.

That in tuberculosis as in pneumonia and typhoid, while the chief seat of toxin producton is in the lungs or bowels, the *chief strain falls upon the heart, and death in the majority of cases is due to toxic heart failure.*

That this undersized and inadequate heart is, like the round, high-indexed chest, the persistence of conditions, normal at about the period of puberty.

That the condition of the heart should be our principal guide, in the diagnosis, prognosis, and treatment of consumption; if the pulse is slowing and strengthening, never mind the lung.

That a persistently rapid pulse without other ascertainable cause, should always rouse suspicions of incipient tuberculosis.

MASSAGE AND MOTION IN FRACTURES.

By GUSTAF NORSTRÖM, M.D. (Stockholm),

NEW YORK.

In the first edition of my treatise on massage, in 1884, I spoke of massage as applied to fractures. What then seemed to be a paradox has become a therapeutical reality. At all times it was claimed that rigorous and prolonged immobilization, employed in the treatment of certain fractures, might cause disturbances in the future action of the nearest joint. A. Paré, J. L. Petit, Warner, Comper, Flajani, Ravaton, Morel Lavellé, etc., had proposed more or less complicated and rational means in order to prevent secondary ankylosis. Their utility was so little admitted that many surgeons in our time would not listen to them. Verneuil has well characterized the anxiety of those who mistrusted the former classic procedures; he calls it ankylophobia.

The advantages of early motion in the treatment of certain fractures were investigated in 1880 by the Surgical Society of Paris. Desprès reported a case to demonstrate its advantages. Verneuil replied that it was wrong to attribute secondary ankylosis to immobilization. The cause of ankylosis is the formation of a fibrous callus. The discussion shows that the surgeons were far from being agreed on the principles of rational treatment of fractures. Marc Sée and Lannelongue were of the same opinion as Verneuil, and always desired immobilization. Lucas Championnière and Marjolin were much less convinced; they admitted with Desprès that in some cases at least one might deviate from the general rule. The same question had been raised outside of France. Menzel of Triest had proposed passive movements every other day in fractures of the raradius; Starke resorted to early movements in fractures of the radius and fibula; Shede proceeded similarly in fractures of the humerus. We here meet with the same doctrinal controversies as in the therapeutics of anthropathies. The fundamental indication in the treatment of the loss of continuity of the osseous system, says Gaujot,[1] is to facilitate by every means the reunion, that is to say, the formation of a solid callus; movements, pressure, and simple effleurage ought to be avoided; the ideal type of apparatus is a muff closed at both ends, which maintains both osseous fragments in rigorous immobilization.

It has not been proven that massage, when properly performed in the beginning, hinders solidification. Very few surgeons are in favor of early applying apparatus to a swollen limb; of immediate immobilization of the fragments which are displaced and separated by a more or less abundant mass of blood. Most of them apply a temporary apparatus and leave it to nature to remove the primary inflammation before resorting to a permanent appliance. It seems to me quite natural to have recourse to massage in order to aid and hasten the absorption of injurious liquids. What we have obtained in traumatic hemarthrosis and in articular phlegmasias followed by effusion, we may likewise achieve here without any more inconvenience than in the former conditions. Thus we see that massage is indicated as an early step in treatment of fractures, serving as an introduction to another one and paving the way for it.

To make early motion an absolute rule is subject to many exceptions; its strict observance presents serious inconveniences in daily practice. Is it possible to formulate rules as regards methodical application of massage and passive movements, which might serve as a *vade mecum* to all practitioners, so that all might follow them without fear, being certain that no danger will follow? We believe not, for each case must be judged on its own merits, but in the majority of cases of simple fracture massage is useful in two stages: (1) at the beginning, because it favors the absorption of sanguineous and serous effusions and diminishes tumefaction and local tenderness; (2) after the removal of the apparatus, if such has been resorted to. It is only through massage that functional weakness, resulting from atrophy of muscles and induration or retractions in the neighborhood of the callus, can be overcome.

It was in my first edition of Traité du Massage that I proposed massage in the treatment of fractures. I am glad that I did tread this path, because nearly all that I proposed has been adopted and massage has become a therapeutic agent of incontestible utility in the treatment of fractures. In 1884, the same year that my work appeared, Berne performed massage in fractures of the fibula. In June, 1885, he stated his theories and the results of his experience in a public lecture at the hospital Bichat. He has since that time published an extensive work on massage, in which I am happy to see my ideas on massage were adopted and confirmed by this distinguished practitioner.[2]

At the first meeting of the French Congress of Surgery, in April, 1885, Tilanus of Amsterdam communicated a comparative study on the treatment of fractures of the patella by immobilization and by means of external coaptation and treatment by compression, massage, and movements. I will speak of this more extensively when I come to deal with these fractures and their treatment.

Dr. Lucas Championnière had already spoken of using massage in the treatment of fractures of the radius and fibula, but it was in 1886, after a large experience, that he made his communication on treatment of fractures with massage before the Société de Chirurgie in Paris. Yet he did not succeed in making it very popular. On the contrary, he had to sustain quite a vehement opposition on the part of his colleagues, who seemed to discuss the matter only from a theoretical point of view. Not possessing any personal experience on the subject, they

made criticisms based only on old, venerable doctrines, which were, if not erroneous, at least capable of complete revision. But we must confess that Lucas Championnière gained the victory and that it is principally due to his influence that massage in the treatment of fractures occupies at this moment the place it really deserves.[3]

The idea had made its way successfully when Maison's[4] and Lapervenche's[5] theses appeared. The method had, perhaps, gone a little too far; but this rapid popularity is by no means surprising. The effects of massage in fractures are excellent, and it is easy to see why. It is not necessary to have vast experience, nor is it necessary to ponder for a long time over the best method to be employed. In the hospitals, the surgical students can very well carry out the necessary manipulations under the guidance of a chief surgeon; the only thing to observe is that different methods of massage, of a possibly harmful character, are not used, as is so often done by empirics, often using awkward brutality.

In fractures, as well as in sprains, luxations, and chronic articular affections, the masseur intends to stimulate absorption of sanguineous extravasations, interstitial effusions, and by *contre-coup* to favor the reunion of the soft parts, to diminish the pain, improve local nutrition, and prevent articular stiffness and consequent atrophies. Nearly all authors who have studied this question admit that these results are nearly always attained.

Thus we see that massage in fractures now answers the numerous indications which partly had been foreseen in 1884. It facilitates the diagnosis, allows us to apply early a permanent apparatus when the latter is indispensable, because massage hastens the absorption of the sanguineous effusion and diminishes the swelling; it prevents future accidents because it does away with lengthy immobilization and stimulates local nutrition. I think, then, that massage applied in fractures will make the treatment enter into an entirely new phase and do away with accidents which almost inevitably followed their treatment under previous methods.

We will now take up its application in different fractures, discussing only those which are of more frequent occurrence.

Fractures of the *Humerus*.—Of all fractures, those of the humerus seem to be the least favorable ones for treatment by massage, and very few surgeons would have the courage to employ it. Nevertheless, in applying it we meet with some most brilliant results.

Fractures of the humerus present several varieties, according to their seat. Although massage is applicable to all varieties, we will here speak only of the fractures in the middle third of the shaft, which are the most frequent and consequently those about which we possess most experience. In such cases, if applied immediately after the accident and before the limb has been put up in an immobilizing apparatus, very gentle massage for about half an hour is of great benefit to the patient. After having repeated this a second time in the first twenty-four hours, the patient will be relieved of a good deal of his pain and the swelling will have been reduced to such a degree that the adaptation of the fragments will meet with much less difficulty than if this procedure of primary massage had not been resorted to. After ten days of immobilization, the bandage is removed and the limb is massaged for fifteen minutes. After the sitting, the limb is again immobilized. This mode of treatment is repeated every day. The bandage is definitely removed after three weeks, after which time the callus will be found sufficiently solid to allow the patient the use of his arm, no stiffness remaining.

Massage in Fractures of the *Radius*.—Many years ago, in 1887, I published a case in which massage had been employed with success on a fracture of the lower extremity of the radius. Still, the application of this procedure had been timed and limited; it had been employed for the purpose of reducing tumefaction and relieving pain; Mr. Gerst, for instance, followed the principle as laid down by Bizet. After the mentioned desired effect had been obtained, he immobilized the limb by means of a plaster of Paris dressing, according to the classical method. Since that time massage has often been applied in fractures of the radius, and particularly at its lower extremity. Lucas Championnière, Gosselin, Tillaux, Gurlt, and others, have studied the question of massage and immobilization in these cases. Schede, from Hamburg, returned to it in 1884 at a congress of German surgeons held at Berlin. He insisted upon the frequent occurrence of partial ankylosis of the hand and finger joints, of adhesions of the tendons to their sheaths, and of atrophy and retraction of the muscles. Nothing like this had ever been observed in cases of paraarticular fracture of the radius treated by mobilization and massage. In my notes I have set down twenty-four personal observations on fracture of the radius, most of them affecting its lower extremity, treated by massage and relative mobilization. Solid and complete union after fourteen to eighteen days. We have long ago abandoned the ideas of Malgaigne, who allowed his apparatus to remain for thirty days.[6]

Fractures of the radius are, as everybody knows, most common, and those seated in its lower extremity (Colles' fracture) are the ones about which I have the most experience. Massage is easily applicable in the treatment of this fracture, on account of the more or less superficial seat of the injured bone, the masseur not being obliged to work here through thick layers of interposed muscular tissue. There ought not to exist any fear of causing a displacement of the fragments, as these fractures as a rule are impacted.* Massage should not be too deep, on account of the often extreme sensitiveness not only at the seat of the fracture, but also of the joint itself, as well as of the sheaths of the tendons. But massage in the shape of effleurage is not the only maneuver to be employed. This has to be combined with passive movements executed not only in the direction of the flexion and the extension, but even in that of supination and pronation; they ought to be slight at the beginning, but as the treatment progresses one ought gradually to increase the motion.

I do not advocate the application of any other apparatus in the treatment of fractures of the radius than a roller bandage around the joint. The hand is suspended in a sling. This suspension is convenient, at least during the first days, when there is a great tendency to swelling of the arm and the hand. The arm is taken out of the bandage and massaged once a day, supported by an assistant or lying on a cushion. After a fortnight or three weeks the patient has entirely recovered; the callus has become solid. It is very rare that one is obliged to prolong massage after this time. One finds then that the wrist is perfectly supple, with the integrity of all the movements, and that the patient is able to use his arm perfectly well.

Fractures of the *Olecranon*.—I think that of all fractures, those of the olecranon most frequently

*In some exceptional cases there is displacement of the fragments, the lower one being pushed behind the upper one. These ought to be treated after the mixed method (mobilization and immobilization).

cause vicious union of the fragments. But in the opinion of Lucas Championnière the fibrous scar is much more perfect than that we observe in the repair of the patella; the one of olecranon is at the same time shorter and more solid, and consequently interferes less with the various movements of the joint. But there is another condition that interests us here more than the condition of the fracture itself, and that is the changes taking place in the neighborhood of the fracture. I refer to the humero-ulnar joint, which on account of the violence of the shock which has brought about the fracture, has become the seat of a more or less abundant effusion, a real traumatic synovitis. Besides, there is a rather rapid atrophy in the triceps, promoted by its being torn from its principal insertion, not to speak of the one produced later on from unknown cause, as in all extensors in the neighborhood of any joint which is the seat of an effusion. These complications—stiffness of the joint, as well as the inability to move the limb—which were the regular consequences of the old classical treatment, are never produced if from the start we apply massage, followed by subsequent passive movements. Although the posterior portion of the joint is the one which is principally affected, massage ought to be applied to the whole circumference of the elbow, even in the line of the fracture. On account of the great sensitiveness of the seat of the fracture, massage must be applied more gently over this region than in the neighborhood. To the triceps muscle massage can be applied with a certain energy from the beginning.

It is well known that in all affections of the elbow, traumatic or not, the re-establishment of the normal extension often leaves much to be desired. This may in some cases be hard to explain, but in most cases it is no doubt due to the imperfect repair in the insertion of the triceps to the bone. The passive movements of pronation and supination ought not to be forgotten. Passive extension has to be begun in the first days after the accident, as soon as the pain, much reduced by massage, allows this maneuver. There is no fear, as one may believe, that the passive motions may produce some trouble in the repair of the fracture, provided they are performed carefully and without any violence. Flexion must be carried out with special caution, as it may tend to separate the fragments. Moreover, Lucas Championnière lays stress on the well-known fact that movements of this kind come back very easily in a limb as soon as this has been massaged. Therefore the surgeon does not need to give flexion the same careful consideration as extension. It is then not necessary to resort to this movement before the fourteenth to the twentieth day after the accident. There is absolutely no need of an apparatus to put the limb in, as there is nothing to immobilize. Even the advantage of applying a roller bandage, as advised by me in speaking of fractures of the radius, may be open to discussion. In the beginning, if the swelling is considerable, it is good to have the patient lie down, the elbow resting on a cushion. But after some days this is no longer necessary, the patient carrying his arm suspended by a sling and walking about. Proceeding in this way, one reduces the healing to half the time required under the old régime. Under the old plan of treatment, several months were required to restore the elbow to its normal functions, and even then it was only seldom that this returned completely. The same applies, in a still higher degree, to the atrophy of the triceps with its consequences. After eight weeks the cure is generally complete. The elbow is now supple, and the patient is able to make all movements and without any pain. The repair varies a great deal with different individuals. With some of them the union is entirely complete and to such a degree that one does not notice any depression on the bone, corresponding to the line of fracture, while in others there remains a greater or lesser gap between the fragments. One is often able to speak of a real cure under this method of treatment by massage, while under the old method of immobilization this is far from true. Furthermore, we may state that, in fractures at the olecranon, as in fractures at the lower extremity of the fibula, no treatment at all would be preferable to the former treatment of immobilization. I could cite several cases from my experience in order to illustrate this fact; but I wish to quote only one, a particularly illustrative fracture of the olecranon:

A boy, ten years old, fell upon his elbow two months before his mother, an American lady, consulted me about him in Ragatz. This accident was followed by an enormous swelling of the joint, which never disappeared completely. With the exception of compresses of cold water, no special treatment was resorted to; no fracture of the bone was diagnosticated, and it was assumed that only a violent contusion of the elbow existed. It was not until four or five weeks after the accident, when most of the swelling had disappeared, that a fracture of the olecranon was detected. When I saw the patient for the first time there was a gap of one centimeter between the fragments, and these were united by a rather soft, fibrous tissue. The humero-ulnar joint was more or less stiff, although not quite so immovable as one would suppose on account of the relatively long time that had elapsed since the accident. Besides, all the muscles of the upper arm, and particularly the triceps, were slightly atrophied; yet the little patient was able to use his arm fairly well. During five weeks the joint was submitted to daily massage and passive movements—not neglecting energetic massage of the atrophied triceps muscle. When the treatment was stopped the patient had regained most of the faculty of using his arm, yet there was no change in the fibrous union of the fragments. I saw at the same time the two-years-older brother of my patient. He had fallen three years before in the same way as his younger brother, upon the elbow, but only a few days after the accident the diagnosis of a fracture of the olecranon had been made and the arm was treated with the old method of immobilization. The result of this treatment was that he had got a real ankylosis of the humero-ulnar joint, which permitted only a mobility hardly perceptible.

Fractures of the *Diaphysis of the Femur.*—It is easily conceivable that on account of the great tendency of displacement of the fragments in the fractures of the femur, massage as a secondary procedure, viz., when the limb has been put in an immobilizing apparatus, cannot rationally find its application. Notwithstanding the high authority of Lucas Championnière, I am sorry not to be able to agree with him, when he expresses himself as follows: "The patient is always put in the extension apparatus devised by Hennequain. If one likes to apply massage to the extended limb—opening the apparatus from time to time—the massage cannot bring about any new displacement of the fragments. The latter, although never absolutely immobile, cannot be made to override owing to the extension; therefore it is evident that no displacement, no deformity, can result from this procedure."* However this may be, it seems to me that the extension of the limb can by no means be pushed so far that it could not allow any further displacement of the

*Loc. cit.

fragments by the pressure communicated to them by massage. But if I hold that massage is not useful in these fractures as a secondary treatment, I find from experience that no objection exists to its application before the member has been put on the extension apparatus. Thanks to this primary massage and its analgesic influence, the pain may be greatly decreased and the swelling more or less removed. But, whereas in fractures of the humerus one seance is often sufficient to bring about the desired result, in fractures of the femur several sittings at intervals of a few hours are absolutely necessary.

Massage in Fractures of the *Neck of the Femur* (extra- and intracapsular) can play only an adjuvant part, as the principal treatment is the early immobilization. Lucas Championnière has shown that, contrary to what is generally admitted, the consolidation of the callus in both forms of this fracture is generally very easily obtained. It is not the lack of callus that prevents the patient from walking properly, but the various subsequent deposits in the joints, and the atrophy of the muscles around the articulation. But as the subject of this article is to show the influence of massage in the treatment of different fractures, it would lead us too far, if we tried to open a discussion on this very interesting matter—mobilization or immobilizaton in the treatment of fractures of the neck of the femur.

Massage in Fractures of the *Patella.*—It was for a long time supposed that the reunion of the divided fragments of the patella by an osseous callus was impossible. If this were true, the problem might be easily solved. We need not consider the callus, but simply concentrate all our attention on the joint proper, so as to preserve its movements without depriving the leg of its support. The first experiments conducted on animals seemed to confirm the old ideas relating to the nature of the callus. Gulliver could never obtain a perfect osseous union in dogs, when the fibrous capsula was torn. Astley Cooper was no more successful.[7] Since that period facts have accumulated showing that union really can occur. The possibility of osseous union is therefore not to be disputed, although it may not take place very often, or rather, more as an exception. But the main object is to know whether it presents enough advantages that we should strive for it, whether, after osseous union has taken place, the femoro-tibial joint is just as useful as before.

Surgeons have not considered the question from this standpoint; they have, and not without foundation, taken into consideration the inconveniences caused by too loose fibrous union. Péan says: "The mode of reunion causes an invincible obstacle to certain professions." The same author adds: "It is true that I saw in the service of Desormeaux a porter, who had not lost any of his strength, though the separation of the fragments was considerable." Others have observed the same. It is desirable that the question schould be definitely solved. Is an excessively long, fibrous band more inconvenient than a very short mode of union? Is the stiffness only temporary, and can we hope that it will disappear spontaneously? On the solution of this problem depend the indications of massage and passive movements in fractures of the patella. The first may be applied in two different ways: (1) At the beginning, as in fractures of the olecranon, in order to modify immediate articular inflammations, pain, effusion, and tumefaction. (2) It is used, when the immobilizing apparatus has been removed, to restore elasticity to the capsule and ligaments, and to cause the disappearance of hyperplastic products left by immobilization. The third method of procedure is much more bold than the preceding ones. No attempt at bringing the fragments together is here made. What the surgeon tries to avoid is future immobilization; he does not consider the union. Metzger, who has introduced this mode of treatment into our therapeutics, does not seem to have great confidence in surgical procedures, which are intended to limit the extent of the new method in uniting the fragments. Whatever may be done, the patient will always retain a deformed knee joint. The best he can do is to get accustomed to the affection and disregard the effects as much as possible, making use of flexion, extension, and support. The communication of Prof. Tilanus of Amsterdam, read at the first meeting of the Congress of French Surgeons, in April, 1885, brought the attention of the French medical body to this subject. The statistics compiled by Tilanus show, as he claimed, that fractures of the patella are more easily cured by compression, massage, and passive movements, than by immobilization. At about the same time Lucas Championnière and Tripier of Lyons tried to push the method so highly spoken of by the "Amsterdam School" to the front. A patient in Tripier's clinic with fracture of the patella was cured without the ordinary immobolizing apparatus by compression, massage, and articular movements. Leonardon Lapervenche has successfully performed massage in fractures of the patella, in the various clinics he attended. Metzger's bold intervention and Tilanus' communication form the foundation of a new method of treating fractures of the patella.

Ever since Hippocrates, surgeons have tried, in fractures of the patella, to restore the morphological integrity of the limb and to induce the formation of union in the divided bone. The new school regarded the matter from a different standpoint. Little importance was attached to the union or separation of the fragments, if the patient was able to walk and use his lower limb after, as well as before, the accident. It is better to possess a leg that can be used, that can be flexed and extended with the patella split in two, than to have a rigid and impotent leg with the patella intact. The occurrence of secondary affections is the same as in all intra- or para-articular fractures. They are muscular atrophy and rigidity of the joint. The object of movement and massage is to prevent atrophy of the crural triceps, to favor absorption of the synovial fluid, and prevent stiffness of the joint.

It is now important to find out whether the object in view has really been achieved, whether the femorotibial joint with a fractured patella is as good as one in which this bone is intact. Surgeons are far from being unanimous on this point. After having excited a keen interest, almost enthusiasm, this new method has arrived at a less brilliant stage. Are we to reject massage in the treatment of fractures of the patella because it is not always the sole indication? By no means. Even if we desire to obtain the best possible union, massage of the joint, as well as passive movements, executed in the beginning very slightly in order to prevent the separation of the fragments, later on, when the union has gained more solidity, with greater amplitude, may be used as adjuvant means. On the other hand, we must never lose sight of the condition of the crural triceps; we must overcome its atrophy, which is the most important cause of future functional disorders.

The method of Metzger seems, except in some very few cases, to have been entirely abandoned. The interposition of the fibrous tissues here, as in immobilization, offers an invincible obstacle to the union of the fragments, which remains insufficient and fibrous. No wonder that one has resorted to

application of sutures, as this method only is able to produce as osseous union—at least in a great many cases. Moreover, the application of sutures gives, at the same time, occasion to lay open the cavity of the joint, in order to remove the coagula of blood which one sometimes meets there even after weeks, keeping up an irritation of the synovial membrane. Proceeding in this way, one does not fail at the same time to act favorably upon the quadriceps femoris, removing any irritation originating from an affection of the joint and leading to an early atrophy of the muscle. Lucas Championnière, who at the Hospital St. Louis in Paris, had occasion to treat a great many fractures of the patella, has finished by adopting the suture method as the almost exclusive treatment of fractures of the patella, regarding immobilization alone as much inferior in establishing a firm osseous union.

Massage in Fractures of the *Lower Extremity of the Fibula.*—Nearly all the authors, including myself, who have studied massage applied in fractures, mention cases of fractures of the lower extremity of the fibula in which massage has achieved wonderful results. Thus Maison, Leonardon Lepervenche, Rafin,[8] and others, have published several cases treated with success after this method, but it is Lucas Championnière who, even here in his already cited work, has laid down the results of his great experience. In all of these cases, immediate inflammatory changes were prevented and union was easier than when treated by immobilization alone.

According to Malgaigne, complete union is brought about in thirty days, provided the position of the limb be not altered. But it is not only because the time necessary for union is shortened that massage is superior to any other method of treatment applied up to now. Everybody knows well the state the patient is in, when, after some weeks of immobilization, the plaster dressing is removed and he is allowed to walk. Not only tibiotarsal articulation, but often also the small joints of the foot, are the seat of an effusion, particularly in old people, and in those who suffer from rheumatism. Besides, all the muscles in the neighborhood of the joint are found in a condition of more or less marked atrophy. None of these unpleasant results will happen if you pursue the new method. When this is employed, the patient at the time he begins to use his limb experiences no difficulty at all.*

The analgesic influence of massage must not be underestimated, either. Thanks to the beneficial effect of effleurage, the pain at the seat of the fracture, as well as the pain which resides in the tibiotarsal articulation and the neighboring soft parts, disappears after a few days. It really seems as if the sprain, which almost always complicates the fracture, did play the principal part, and the fracture were of only secondary importance. How often has not a fracture been mistaken for an ordinary sprain, and been cured without any special treatment of it, to the great delight of the patient? There need not be the slightest apprehension that a displacement of the fragments will occur in these cases, if massage is properly performed. Even if in most cases, owing to the well-known deformity of the foot resulting from a fracture, it is not difficult to discover the existence of a fracture of this kind, still it is not always easy. The characteristic displacement may be very little pronounced, and the extensive swelling of the tissues, may prevent discovery of the seat of the fracture. After massage and the removal of a great deal of the edema, it will often be possible to make a positive diagnosis after a single séance.

The same treatment may be applied with similar good effect in cases in which there is a laceration of the internal maleolus, or where there is a real bimalleolar fracture. After every séance resort to passive movements. These must be performed carefully, particularly the first ones, avoiding great excursions. The only necessary apparatus is a roller bandage, similar to the one used in the treatment of fractures of the lower extremity of the radius, which is to be removed before every séance and to be reapplied after it. For a fortnight the patient is not allowed to walk. After this time he may be allowed to walk short distances.

The duration of the treatment in my cases lasted three weeks. In one case, where I had to deal with a very young man, eighteen days were already sufficient to obtain a cure. It is to be regretted that the great majority of physicians still continue to immobilize such fractures for weeks, to leave stiffness very difficult to overcome, and from which the patient will be a sufferer all his life. In these fractures, and perhaps more than in others, we may affirm that the sooner massage begins the more perfect will be the result.

Although it is true that in the great majority of cases sprain complicates fractures of the lower extremity of the fibula, there, however, exist certain varieties, which do not affect the articulation proper. But in these cases the joint is so near the line of the fracture that it suffers from the trauma, although no violent lesions are to be found in the joint or its immediate neighborhood (Lucas Championnière). Just as in fractures of the radius, no apparatus which deserves that name is to be employed; a roller bandage, removed every day to have the limb massaged, will be all that is required for our purpose, the patient resting on a couch. It is only in cases where there is a great tendency to displacement of the fragments that it would be necessary to immobilize the limb between the séances of massage. Passive movements are resorted to after the second or third day. Cautious movements of extension and flexion are executed after every séance. Moreover, as I have already said, the joints of the foot and toes often suffer in these affections, and it is necessary not to forget to massage and move these also after some days. Not longer than after fourteen days, walking may be allowed, moderately, of course, in the beginning. Exception to this general prescription is made in those cases in which particular conditions have necessitated the application of an immobilizing apparatus. After three weeks of treatment the patient is able to walk about without using any support and without complaining of any pain or inconvenience in his limb. Only very rarely slight pain remains, necessitating some occasional séances of massage.

Massage has also been used in fractures of the shaft of the fibula. It is clear that it cannot render the same services here as when applied to fractures in the neighborhood of the joint. It may be useful during the first days to ameliorate the disorders which follow the solution of continuity of the osseous levers, to alleviate the pain and to hasten the disappearance of the swelling; later on it may be used with beneficial effect to overcome the persisting functional weakness.

*I can recall, among other cases, theat of a diplomat, high in rank, who having been treated by a great surgeon in Paris, according to the old method, was not free from his trouble until five months had elapsed after commencement of treatment, while in a similar case that I treated at about the same time, in the person of another diplomat of about the same age, the treatment with massage and passive movements led to a complete cure in the course of only one month.

SYPHILITIC EMPYEMA OF THE ACCESSORY SINUSES OF THE NOSE, WITH A REPORT OF FOUR CASES.*

By JOSEPH H. ABRAHAM, M.D.,

NEW YORK.

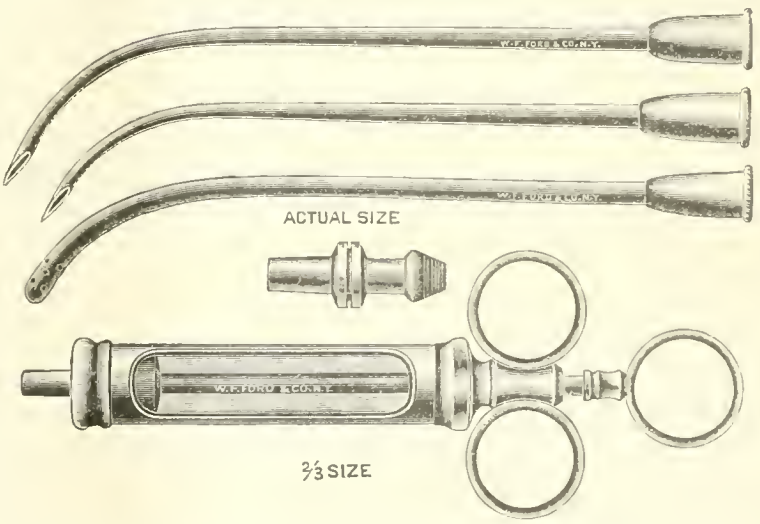
The oft-repeated assertion that syphilis attacks all organs and tissues of the body, proves true, in as far as laryngorhinology is concerned. Practical experience has time and again demonstrated the positive clinical fact that luetic lesions may invade any part of the upper respiratory tract in one degree or another; and furthermore, tertiary lesions seem to prefer the nasopharyngolaryngeal cavities and tissues to those of any other part of the body. This is especially true of syphilitic ostitis and periostitis of the nasal and superior maxillary bones. Syphilis of the accessory sinuses is rather uncommon. My experience has been limited to four cases. In these cases the suppuration was undoubtedly due to the breaking down of a gummatous periostitis and ostitis and secondary infection by the pathogenic bacteria. In all of these cases the pus was examined bacteriologically, and it was utterly impossible to isolate the specific microorganism on account of the varied forms of cocci, bacilli, etc., that were present. Had the patients followed their physicians' advice and continued under their care and treatment, I feel assured they would never have suffered from such marked tertiary lesions.

The chief symptoms in these cases were those of nasal discharge and fetid breath. Pain was not a constant symptom, but was always present during mastication, and was located along the upper row of teeth and antrum; at times it extended upwards along the inner canthus of the eye. Pus was present in all of my cases. In consistence it was thick and creamy; in quantity, very abundant; in color, a bright yellow; and its odor extremely fetid, foul, and disagreeable—so much so that after cleansing and syringing the nasal sinuses it was necessary to ventilate the room before the entrance of another patient. Two of the patients complained of gastric disturbances, which were probably accounted for by swallowing the purulent discharges.

In diagnosing these cases I relied upon the presence of a purulent accumulation in the middle meatus anteriorly, transillumination, and puncturing and aspirating the maxillary sinus through the nasomaxillary or inner wall of the antrum. On the latter method I place the greatest reliance in diagnosing empyema in the cavity of the maxillary bone.

The presence of pus is detected by first thoroughly cleansing the nasal cavities, and then directing the patient to incline his head to the opposite side for a minute, then downward and forward. On again examining the region of the middle meatus, if pus is present it will be detected adhering to the inferior surface of the middle turbinate anteriorly. On transilluminating the maxillary antrum a positive result was obtained in all of my cases, *i.e.* a darkened area over the maxillary sinus. We all appreciate that the presence of any new growth or other abnormality within the antrum will give a positive reaction to this method of diagnosis. Therefore the main point to differentiate in all of these cases, was the presence or absence of pus in the antrum. That leads us to the method of diagnosis, which I personally believe gives us the most positive results, and that is puncturing and aspirating through the inner wall of the antrum.

As several instruments have been devised for this operation, with advantages and disadvantages, I wish to present a set of needles and a syringe, which, in my hands, have proven the most practical, the least dangerous, and the most successful. They are made by drilling a hole through a solid graduated bar of steel, then filing to a point and curving the tip. The proximal end, as you can readily see, is twice the diameter of the distal



end or tip, combining the strength, delicacy, and durability, which I personally consider a great improvement upon the Maurice Schmidt-Schoetz trocar-cannula.

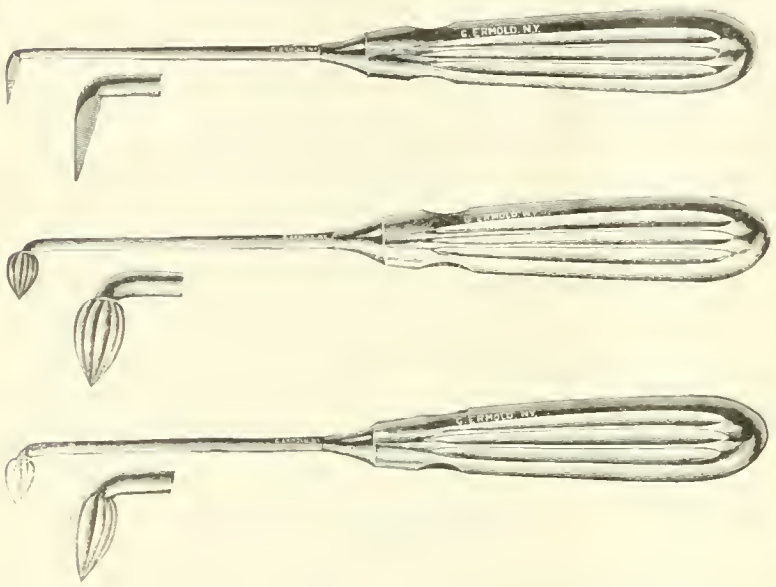
After thoroughly cleansing and cocainizing the middle meatus, the needle is directed to the middle meatus, just below the anterior ethmoidal turbinate, the point hugging the upper convex surface of the inferior turbinate, about three centimeters from the floor of the vestibule. The point should be directed toward the inner wall of the antrum, then with gentle pressure outward, with a distinct downward inclination. The point of the instrument will enter the antrum without the least pressure. By withdrawing the piston of the syringe, pus will gradually flow into the barrel, if present. In some cases it may be necessary to change the direction of the point, by gently turning forward or backward. If we fail to detect pus and are still in doubt, then puncture through the inferior meatus, always using the smaller of the two needles, which pro-

*Read in the Section on Laryngology of the New York Academy of Medicine, November, 1905.

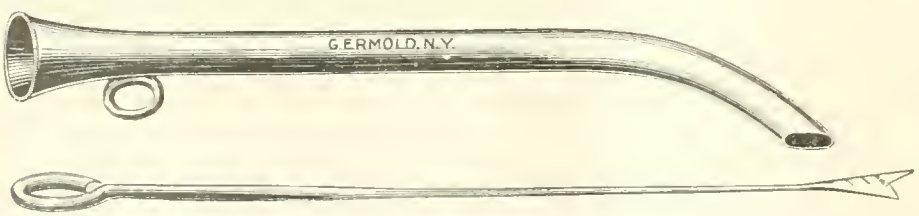
cedure is equally simple and requires no detailed description.

In describing the treatment of these cases, it is unnecessary for me to dwell upon the so-called specific remedies, their indications, action, and method of administering. Suffice it to say that the iodides were given immediately, beginning with small doses of five grains, three times a day, and increasing daily, one grain at each dose, until all physical signs of the gummatous infiltration had entirely disappeared. Daily flushing of the antrum with an antiseptic solution and cleansing of the intranasal space, was the only local treatment at this stage of the disease. In about two months all traces of the gumma had disappeared in the nasal cavity, but there remained a constant purulent nasal discharge, with a fetid odor, and in order to relieve the patients of these distressing and disagreeable symptoms, I found it necessary to open, curette, and drain the antrum, and to remove the necrosed ethmoidal tissue.

Operative procedure upon the ethmoidal cells



is somewhat simple. After thoroughly cocainizing with a five per cent. freshly prepared solution of cocain, the necrosed bone and granulation tissue are removed with a nasal bone forceps, curettes and snare. After curetting and cleansing, no hemorrhage being detected, blow upon the surface a



thick layer of thymol iodide and plug the nasal vestibule with antiseptic gauze. In some cases it may be necessary to plug the ethmoidal region with iodoform or other gauze, on account of hemorrhage, although in my series of cases plugging was unnecessary. The postoperative treatment is simply cleansing the surface with an antiseptic solution and general systemic treatment.

Operative procedures upon the antrum were confined entirely to the inner wall of the antra, through the inferior meatus, by puncturing and drilling with graduated sizes of burrs, and, if necessary, enlarging with forceps and curettes, making an oval-shaped opening, about 1.5 to 2 cm. in size. Through this opening the antrum was thoroughly packed with iodoform gauze, one-half inch wide, through a nasal gauze packer.

On removing the gauze, the cavity was irrigated through the perforated antral tube, drained, and zinc sulphate solution of varying strengths injected, and then thoroughly dried. In one case, an organic silver solution was injected, with very good results, and its application in increasing strengths was free from pain, which is indeed, a great comfort to the patient. In my series of cases it was not necessary to remove any portion of the inferior turbinated body.

Mr. A., aged forty-two; born in America; married; merchant by trade. Consulted me August 24, 1901, complaining of a slight pain in the left lateral wall of the pharynx during the act of swallowing, and of a constant unilateral nasal discharge, with a foul and disagreeable odor, of which he and his friends were perfectly conscious; a constant full sensation along the cheek bone, with pain along the upper lateral row of teeth, especially during mastication; headache over the eye. All of these symptoms were unilateral and localized on the left side of the face. On arising the patient complained of nausea, and at times vomited. Anorexia was a very marked symptom.

The patient was a strong, well-developed specimen of manhood, who contracted a genital chancre fifteen years ago, and was under the care of his family physician for four years, and reacted well to a course of specific treatment. He never complained of a single luetic symptom until within a few days of consulting me; but, as the physical examination will reveal, it is indeed surprising that so intelligent a patient should allow so marked tertiary symptoms to develop before consulting a physician. Examination of the pharynx—situated upon the left posterior faucial pillar, and extending laterally on to the wall of the pharynx, was an oval-shaped tumor, 2.5 cm. in its vertical diameter, and 1.5 cm. in its transverse diameter, with an irregular ulcer, situated about its center, covered with a dirty, purulent secretion. The rhinopharynx was bathed in a yellowish, purulent secretion, coming from the left posterior nasal cavity. The right nasal cavity was normal; the left nasal cavity was filled with a profuse foul-smelling discharge. After thoroughly cleansing the nasal cavity, the middle turbinated and ethmoidal cells were found to be twice their normal size, due to a tumor which practically eliminated all of their anatomic relationships. Transillumination of the antrum was positive. Puncturing and aspirating through the inferior meatus was also positive—so much so that words are inadequate for me to describe the sickening odor that penetrated my office when the pus was emptied, and it required liters upon liters of a strong formalin solution to neutralize the stench. Treatment: The iodides were immediately administered, beginning with five grains three times

a day, and increasing two grains at each dose daily. The antrum and nasal cavities were irrigated with an antiseptic cleansing solution. Pure chromic acid was applied to the broken down pharyngeal gumma. In one week a marked improvement of the gumma was noticed, and in three weeks all signs of the tumor and ulceration had disappeared, except the cicatrix. Marked improvement was noticed in the nasal symptoms, and on November 14, under anesthesia by 4 per cent. freshly prepared cocaine solution, I removed the ethmoidal cells and the major portion of the middle turbinated bone with forceps, snare, and curette, and drilled an oval-shaped opening into the antrum with burrs and enlarged with forceps, curettes, and chisels. Then I curetted the cavity and packed with iodoform gauze. After all inflammatory symptoms had disappeared following the operation, the antrum was irrigated and then sprayed with zinz sulphate solution, beginning with 2 per cent. and gradually increasing to 15 per cent. solution. The nasal cavities should be thoroughly sprayed with some bland, non-irritating oil, preferably alboline, before applying the zinc solution. The patient made an uninterrupted recovery, and was discharged January 1, 1902.

Mr. B., aged twenty-five; single; commercial traveler; born in America. Consulted me November 9, 1904, complaining that he had been unable to breathe or blow through the left nostril for about four weeks; there was also a nasal discharge on the same side. The left eye watered freely, and the tears ran over his face. Pain under the eyes most marked at the inner canthus. He denied absolutely and most emphatically that he ever contracted syphilis in any form whatsoever. Examination of the right nasal cavity revealed a bulging and edematous septum, with a pin head ulceration, situated at the antero-inferior angle of the septum. On the left side it was absolutely impossible to outline the anatomic relationships, on account of the cavity being filled with a large, ulcerating tumor, which filled the whole interior of the cavity. With a probe, necrosed bone could be detected on the septum and inferior turbinated bones. Anteriorly the probe passed through the septum, entering the right side, where the ulcer was detected.

Transillumination of the antrum was positive. A small piece of tissue was removed for microscopical examination, and immediately iodide of potassium was administered, as in the preceding case. Before the pathologist's report was received, a clinical diagnosis of syphilis was made. The growth began to fade away as if by magic under the iodide, and during its gradual absorption, adhesions could be detected between the middle turbinate and septum, with pus oozing from between the middle meatus. Immediate operative interference was indicated in this case on account of the gumma pressing on the lacrymal duct. Therefore, in five days I removed the major portion of the ethmoidal cells and middle turbinate, broke down the adhesions, and then relied upon the iodide of potassium for further effect, as it was necessary for the patient to leave the city on account of his occupation. During his absence he was treated by several specialists in other cities. In this case, on aspirating the antrum, no pus was obtained, but a marked resistance to the entrance of the probe was detected. No operation upon the antrum was undertaken, although I fully believe a gumma filled the antrum. The case progressed most favorably under the iodides, and a complete absorption of the gumma was obtained, and the normal function of the lacrymal duct was restored. This patient was discharged, cured, on May 1, 1905.

Mrs. C.; age, thirty-seven; married; one child. Consulted me in October, 1902, complaining of a swelling of the roof of her mouth, pain of gums and at roots of teeth, inability to breathe through either nostril, bilateral, foul-smelling nasal discharge, severe headache, and pain over entire face, which was most acute on the left side. Loss of appetite and gastric pains were present. She feels very weak, and finds it impossible to assume her usual daily labors. She was treated by her family physician for several weeks, and at his suggestion consulted me at the New York Polyclinic Hospital, for diagnosis and treatment. The general appearance of this poor woman was pitiable. A thin, pale, emaciated subject, who was so weak that walking was an effort; a typical mouth breather, with bulging alæ nasi. On tilting her face upwards and backwards, and without the use of a nasal speculum, both nasal vestibules were seen to be completely obstructed by a large polypus. Under the left eye and near the inner canthus, a broken-down oval-shaped tumor, 2 cm. in diameter, could be seen, discharging pus profusely. With a probe, the left antrum was entered without any effort, and necrotic bone detected in all directions. With a speculum and probe, both nasal cavities were found filled with polypi, and here and there necrosed bone. The cartilaginous septum was perforated. On opening her mouth, an oval-shaped tumor, involving the major portion of the left alveolar and palatine process of the superior maxillary bone was disclosed, extending inward nearly to the middle line. Such, in a few words, is the picture of the unfortunate individual whose deformity and whose sufferings were horrible.

The patient denied syphilitic infection; but on account of her weakened condition, I decided upon immediate operation, and removed a mass of polypi and necrosed osseous tissue from both nasal cavities, partially restoring nasal respiration. Iodide of potassium and tincture of ferrichloride were prescribed, beginning with five grains of iodide of potassium, and increasing one grain three times a day. Hygienic and dietetic treatment were also prescribed. A portion of the growth was examined microscopically, and the pathologist reported it to be syphilitic. The patient returned in one week, and I shall never forget the changed expression from one of impending collapse to that of marked improvement. As the iodides were gradually increased, the tumor slowly diminished. On account of her anemic condition, gastric irritability and weakened stomach, it was necessary to administer the iodides in peptonized milk, after the method advocated by Dr. Delavan. This was necessary when she was taking twenty-four grains of iodides. She continued to improve, and I managed to push the drug to forty grains, three times a day; but as her gastric symptoms increased, I changed the iodide of potassium to iodide of sodium. During this time the nasal cavity was cleared of the polypi and diseased ethmoidal cells, the left antrum opened through the inferior meatus, curetted, irrigated, and packed with iodoform gauze. The patient improved in weight and general appearance. The broken-down gumma of the

face disappeared, and the gumma of the inferior maxillary region gradually faded away.

My ambition was to obtain a complete recovery, but as the patient lived in a neighboring village, and her household duties demanded most of her time, her visits became few and far between. In four months I lost sight of her entirely, and no one regrets more than I my inability to give a report of complete recovery, and a more detailed account of the case. I requested her to bring her husband for examination, which request was never fulfilled. The young daughter, aged six years, was rather anemic, but otherwise a healthy child.

Mr. D.; aged thirty-five; actor; married; no children. Consulted me May 16, 1905, complaining of constant nasal discharge on the left side, with marked pain in the cheekbone, and especially on mastication. He contracted a genital chancre fifteen years ago, and was treated by a specialist in genitourinary diseases for three years, with good results. Two years ago he consulted a prominent rhinologist, who diagnosed syphilitic empyema of the antrum, and operated on the left antrum, drilling into the antrum through the inferior meatus. The cavity was curetted, packed, and later irrigated with antiseptic solution. On account of the patient's profession, which frequently called him out of the city for a considerable length of time, he was advised to irrigate his antrum, and obtained fair results. On May 16 he consulted me, and on examination I found a slightly inflamed mucosa, with a purulent secretion in the left nasal cavity. Transillumination was positive, and on irrigating through the previously-made opening, foul-smelling pus was obtained. I advised curettage, and under cocaine the antrum was gently curetted through the patulous opening in the inner wall. Argyrol was injected, beginning with a 10 per cent. solution, and gradually increasing to a 30 per cent. solution, with marked improvement. As I was leaving the city on May 25, Dr. Levy was kind enough to take charge of this patient, and I herewith present his report; he says: "When I first saw this patient, the discharge was of a purulent type. On washing out the cavity, three days later, I found that the discharge had lessened considerably, and the character had become mucopurulent, with the mucous element predominating. A silver preparation was used daily, preceded by washing the cavity with a mild solution of boric acid, and the discharge became less each day until finally, on the fourteenth day, it was found to have ceased entirely, and the first washing returned clear. The patient was entirely relieved. On the whole, this case demonstrates very clearly the efficiency of thorough irrigation and medication, with a combined astringent antiseptic."

In conclusion, I think we are justified in claiming that no syphilitic patient is free from the possibility of tertiary manifestation, in one form or another, even after a thorough course of antisyphilitic treatment, lasting two years or more; therefore, all syphilitic patients should be advised to consult their physicians every one to three years subsequent to their treatment. Secondly, a positive diagnosis of empyema of the antrum of Highmore can be arrived at with the aspirating needle, properly applied; thirdly, syphilitic empyema of the accessory sinuses quickly responds to specific treatment and conservative surgery; fourthly, the administration of iodides in small doses, and increasing one grain three times a day, has proven of greater value in my hands than large doses rapidly increased; fifthly, unless urgent symptoms demand immediate operation, we should delay operative interference, in order to obtain as great an absorption of the gummatous infiltration with the iodides as possible.

616 Madison Avenue.

SPLENIC LEUKEMIA.

By H. J. THOMPSON, M.D.,
LA PORTE, IND.

Miss E. H. came to me August 24, 1904, giving the following history: Age, thirty; single; nationality, American; occupation, teacher.

Family history: Father living, age over seventy; mother died of organic heart trouble in January, 1904, age not given; one sister died of typhoid fever in 1901; one brother died of typhoid fever, time not given. The patient has one sister living who is in excellent health.

Past history: Illness, none severe. In December, 1901, had, as she expressed it, nervous spasms, the result of overwork and of the shock occasioned by the sudden death of a sister.

Present history: In November, 1902, she fell backward, striking her back on a stone, and was ill for a few days. In December, 1902, she awakened one morning and discovered she had lost the use of her lower limbs; she had no pain in them but was confined to her bed for three weeks. Some time later she continued teaching but had to be carried to the schoolroom each day and had but little use of her limbs until June, 1903. During that summer her health was only fair. In September, 1903, she went back to teaching. Her limbs were weak and about this time her left side began to pain; she also noticed a growth in the left side of the abdomen; it was painless but somewhat tender, but the patient did not stop teaching. In December she caught a severe cold and was in bed two weeks with grippe, all this time gradually growing weaker.

In January, 1904, her mother died very suddenly, leaving the patient in a state of collapse; she was in bed for nearly eight weeks, had an attack of gastritis with severe attacks of vomiting which became almost continuous, and was very nervous and depressed.

In April, 1904, had an attack of heat prostration and was in bed for five weeks, in fact she was in bed most of the time up to one week before consulting me. She was dizzy and nauseated whenever she stood or tried to walk; she slept very well; her appetite was fair, but she had much nausea; the bowels were constipated; she suffered from continued soreness and pain in the left side; the action of the kidneys was sluggish and there was slight pain when urinating. Her last menstruation was in July of the present year; previous to this patient had been normal with no pain.

Physical examination: Skin very dark in color, especially over the abdomen.

Digestive system: Mouth, stomach, and bowels, negative. The spleen extends down to the crest of the ilium, filling the whole left abdominal cavity, also extending over to the right side of the median line (upper); it is tender on pressure. The liver is only slightly enlarged.

Circulatory system: Blood-vessels and heart, negative; the pulse is of low tension, irregular, and compressible.

Respiratory system: Examination negative.

Nervous system: The patient is very nervous, noises of every description being troublesome to her,

and the least excitement makes her nervous and unstrung.

Genitourinary system: Kidneys and bladder, negative; there is a burning pain in the urethra at the termination of urination.

Examination of urine: Quantity diminished, general appearance very cloudy with precipitation of amorphous urates, probably; specific gravity, 1,020; reaction, acid; albumen, none; sugar, none; indican, a trace; urea, 1½ per cent.

Examination of blood: Reds, 3,250,000; whites, 650,000; hemoglobin, 60 per cent. No differential count made.

When the patient came to me she was having afternoon elevation of temperature of about 2°, with slight difficulty in breathing. Soon after this she caught a cold which lasted several days, was very exhausting to her, and increased the temperature. She was not able to walk at all, and in fact was scarcely able to stand unless supported.

On September 3 her weight was 113 pounds, waist measurement, 34 inches; September 24, weight, 109 pounds; October 15, 113 pounds; November 5, 114 pounds, waist measurement, 32 inches; November 26, 114 pounds, waist measurement 32 inches; December 3, 115 pounds, waist measurement 30½ inches; December 10, 116 pounds, waist measurement 30 inches.

The first Roentgen-ray treatment was given on September 10, and from that time to December 10, inclusive, a treatment was given on an average of one every five days. All treatments were given with the patient lying down, she being unable to sit up. They were given with a moderately hard tube, duration fifteen minutes, distance from four to six inches, and over the splenic region only.

On December 11 the menses appeared for the first time since July 1, 1904. Menstruation continued for six days, with very little pain; the flow was good and fairly normal in color.

As the treatments progressed the stomach symptoms, nausea with inclination to vomit, ceased, the appetite improved, and the bowels acted quite regularly without the use of drugs. She was given strychnine nitrate 1-30 grain three times a day before meals. This was not given continuously, but at stated intervals to stimulate the circulation, the pulse being of low tension and at times irregular, with increased frequency; the strychnine also helped the respiration, which was labored at times.

Immediately after the mensturation ceased the patient returned home and did not have any more treatments until the middle of February, 1905. During her stay at home she had two menstrual periods which were normal in every way. Practically no medicine was given, but she continued to gain in strength and had a good appetite. The latter part of her stay at home she began to walk alone, and finally was able to walk two to four blocks unassisted.

She again came under my immediate charge about February 15, and continued with me until about the first of June. The February menstrual period was delayed one week; there was much pain and soreness over the left side. The March period was delayed with symptoms of intense pain in the left side of the back, which was relieved by the use of the Rogers lamp.

In April she was able to walk and to go upstairs without assistance. Her walks increased in length each day until it was no trouble for her to walk two miles. She continued to gain in flesh and her weight increased to 132 pounds; waist measure was diminished to 27 inches; her appetite was good. There was no stomach disturbance whatever; the bowels acted naturally and sleep was good. The April and May menstrual periods were perfectly regular and with no pain over body. During the last two months that she was under treatment the lower limbs were swollen at times. This was probably due to a rheumatic tendency.

From February to the time of discontinuing treatment, in June, she received three Roentgen-ray treatments a week—all of the second course being given with the patient sitting up. Duration of exposure, location, position, and tube used were the same as in the first course. No treatments were given during the menstrual period in either seance.

The patient left for home about June 1. The trip, which was a long, tedious one that necessitated a change of cars, having long waits, etc., was made alone, the patient feeling no ill effects whatever from the same. During the summer she lived out of doors, was able to care for herself entirely, and assisted in the house as well. Her weight increased to 137 pounds and the waist line was reduced so that she could wear a waist and skirt with belt instead of a loose gown.

At the time she discontinued treatments in June I told her that she should have more treatments and the following examinations made in Chicago during the latter part of August shows the condition still present although very much improved.

Urinalysis.—Qualitative examination: Quantity, 140 c.c.; physical condition, very cloudy; specific gravity, 1019 at 15°; reaction, acid; color, yellow; odor, negative; mucin, sugar, blood albumin, and bile, absent; amorphous urates present.

Quantitative examination: Urea, 2 per cent; indican, very slight trace; acidity, 40°; normal acidity, 30° to 40°.

Microscopical examination: Casts, none; blood, absent; leucocytes, present; epithelial cells (squamous), numerous; uric acid, absent; urates, present.

Analytical report of blood: Percentage hemoglobin, 0.75; number of red cells, 4,160,000; percentage red cells, 83.2; corpuscle hemoglobin index, 84; number white cells, 120,000; polymorphonuclears, 61.5; large mononuclears, 11.5; smalll mononuclears, 20; eosinophiles, 1; myelocytes, 6; nucleated red cells to 100 red cells, 1; characteristics of cells, some irregularity of reds.

Examination of eyes: Right, 15/20+50 cyl.—ax. 90° 15/15. Left, 10/20+50 cyl.—ax. 105° 15/15; normal.

The retinal vessels, veins in particular, were abnormally tortuous—veins twice as large as the arteries, instead of 3 to 2 (normal). In the region between the macula and nerve head were numerous yellowish white spots which the examiner was satisfied were made of leucocytes with a few red cells. These whitish exudates were not in any case surrounded by red margins as is almost invariably reported. There were no such conditions in the left eye. The nerve head in each eye was somewhat hazy due to exudates.

Examination of ears: R. Whisper, 6 inches; watch, 0; forks, c—c2; Renne+. L. Whisper, 15 feet; watch 40/40; forks, all; Renne +.

The ear conditions are no doubt due to exudates, either in the cochlea or in the cochlear nuclear in the medulla oblongata. A number of cases of leukemia are reported in which ear disturbances occurred simultaneously with eye troubles.

Distaste for Alcohol in the Antarctic Regions.—Mr. Wilson, the junior surgeon on the *Discovery* during Capt. Scott's Antarctic expedition, states that the taste for alcoholic drinks dropped suddenly when he and his colleagues entered the ice region, and that the disinclination increased as time went on.

ASPIRATION OF THE TYMPANIC CAVITY AFTER PARACENTESIS; A VALUABLE AID IN THE TREATMENT OF ACUTE OTITIS MEDIA.

By PERCY FRIDENBERG, M.D.,

NEW YORK.

ASSISTANT SURGEON, NEW YORK EYE AND EAR INFIRMARY; ATTENDING OPHTHALMIC AND AURAL SURGEON, NEW YORK CITY CHILDREN'S HOSPITALS AND SCHOOLS, RANDALL'S ISLAND, N. Y.

The once radical dictum of surgery "ubi pus ibi evacua" has long since made way for the principle of removing possible sources of infection, of freely draining areas which might produce pus or other septic material so that, if possible, no evacuation of pus should become necessary. The application of this principle to otology has led to the general use of early and free paracentesis in otitis media acuta, especially in children, and to a recognition of the value of this procedure in the prevention of otitic complications. In spite of an occasional sporadic attempt to retrograde to expectant treatment, Politzerization, and to the *vis medicatrix naturæ*, in spite of theoretical observations as to the benefits of spontaneous perforation, the medical world, and to a certain extent the lay world is fortunately becoming more and more convinced of the benefits of early opening of the tympanic cavity. This education will have been completed when it is generally understood that we do not "open an abscess in the ear," but, in most cases, open the ear to prevent an abscess.

If this object is to be attained, free drainage is of importance, and any measure which will assist the clearing of the tympanic cavity or aid free drainage is of value. The procedure which I am about to submit on the basis of an experience of about six years is the evacuation, by suction, of the tympanic cavity immediately after cutting the drum. For a short time I used the Siegle pneumatic speculum for this purpose, but found it mechanically unsuited besides being difficult to sterilize. Since 1901 I have been using a small glass bulb about five-eighths of an inch wide, shaped like an olive with a very blunt tip. The neck of the glass bulb is stuffed with sterile cotton and attached to a short rubber tube, after both bulb and tube have been thoroughly boiled. Immediately after the paracentesis is made, the glass bulb is pressed against the external meatus plugging the canal hermetically. Suction is then applied and gradually increased until there is a flow of fluid from the middle ear and the glass bulb fills more or less. This suction can be made by using an ordinary piston syringe as an aspirator, or the lips of the operator may be applied directly to the rubber tube. I am aware that this suggestion is rather repugnant to the esthetic sense, but the tube is clean, and the sterile cotton in the neck of the glass bulb prevents anything but filtered air passing up into the rubber tube. The effects of this aspiration by energetic suction are strikingly gratifying. There seems to be less pain after the paracentesis than when an incision only is made. The otitic pain is more promptly and lastingly relieved. The paracentesis opening does not have as great a tendency to become closed, so that a second incision of the drum is less often required. Drainage is much more free. It is quite remarkable to see how much fluid is removed. Several drams is not an unusual quantity. The family physician has on various occasions expressed his surprise that "all that stuff" should have been in the ear. The fact is that "all that stuff" was not in the ear but in the mucous membrane, to a large extent, and was poured out or oozed out into the tympanic cavity in response to the aspiration. In this depletion of the mucosa and the flushing of the middle ear with uncontaminated serum of admittedly antitoxic and bactericidal efficiency I recognize two valuable factors, in addition to the mechanical one of evacuation. The strong negative atmospheric pressure exerted on the paracentesis wound causes its edges to gape and thus counteracts a tendency for it to be occluded by clot and heal together. The removal of inflammatory exudate from the middle ear and the dilution of the contents with blood-serum also works against septic clot-formation. The procedure of aspiration has a certain diagnostic importance, especially in the case of very young children and infants, where owing to anatomical peculiarities and mechanical and optical difficulties we are sometimes in doubt as to whether the drum has been freely opened or not. The application of suction will immediately settle this question.

The method described above has worked very well in my hands. As I have used it invariably for the last few years, I have no comparative statistics to offer with regard to results with and without its application. I know that I very rarely see mastoiditis develop after I have opened a drum early and evacuated the tympanic cavity by suction.

Of course, it must be admitted that mastoiditis is not, or should not be, more than an infrequent complication of otitis media seen at an early stage. My good results may be only coincidence. If so it is a coincidence I should like to see repeated, not only in my own practice but in that of all otologists, to whom this procedure is recommended in the hope that their combined experience may soon determine what value the method possesses.

114 West One Hundred and Twenty-sixth Street.

Pinworms as a Cause of Appendicitis.—David F. Monash states that pinworms are prone to invade the appendix from their habitat in the cecum. Pocketed in the appendix, they and their ova cannot be dislodged, and by reinfecting the intestinal tract which has been thoroughly cleansed for relief of pinworms the disorder is obstinately continued. Accumulating in large numbers, they block the lumen and set up violent spasmodic contractions of the appendix in its efforts to expel the contents, thus coinciding with the clinical picture of appendicular colic. After a portion is expelled relief follows and the colicky attack is not repeated until the appendix is again distended by large numbers of the parasites. Repeated attacks are associated with pathologic changes in the mucosa as shown in cases reported. The sharp, fine-pointed tail of the female worm, which causes irritation of the colonic and rectal mucosa, also produces catarrhal changes in the appendix, thereby paving the way for bacterial invasion of the deeper tissues. Anthelmintic treatment is useless, and in an acute attack even dangerous. Removal of the appendix relieves both affections.—*American Medicine.*

A Case of Chronic Suppurative Inflammation of the Middle Ear, with a Late Development of Serious Mastoid and Tympanic Symptoms.—D. B. St. John Roosa alludes to cases which he occasionally sees in which a patient who has undergone an operation upon the eye suffers from recurrent pain after the after-treatment is well advanced, which the local conditions are not sufficient to explain. Such patients are usually supposed to have at one time in their lives suffered from intermittent fever, and the administration of quinine in these cases subdues and abolishes a pain which the local treatment does not reach. In this article, he reports the history of a patient with chronic suppurative inflammation of the middle ear. There was a late development of serious mastoid and tympanic symptoms. The mastoid was opened, pus was evacuated from the antrum, granular material was removed, and most of the tip of the mastoid was chiseled away. The tympanum was thoroughly curetted. Recovery being delayed, an examination for the malarial parasite was made. The results, however, were negative. Nevertheless, the writer ordered that quinine should be administered. The fever abated, the mastoid and tympanum both healed, and the patient when discharged was in excellent general condition. The writer warns against the temptation to impatience, and further operative treatment for a suspected brain abscess, in cases were thorough local operative treatment does not promptly yield desired results.—***The Post-Graduate.***

MEDICAL RECORD.

A Weekly Journal of Medicine and Surgery.

THOMAS L. STEDMAN, A.M., M.D., EDITOR.

WM. WOOD & CO., 51 FIFTH AVENUE.

New York, March 3, 1906.

HEBOTOMY.

ALTHOUGH it is now something over ten years since Gigli began his efforts to rehabilitate the principle involved in the practically discarded operation of symphyseotomy, by developing the technique of what has come to be called lateral pubic section, or hebotomy, it is only comparatively recently that his claims have received the degree of consideration they seem to merit. Largely through the impetus given by the active proselytizing of van der Velde, the procedure has been tested at a considerable number of European obstetrical clinics, so that Gigli, in addressing the Viennese Society of Obstetrics and Gynecology in May, 1905, was able to report eighty-five cases of hebotomy, and Bauereisen has more recently (*Münchener medizinische Wochenschrift*, December 19, 1905) collected enough others to bring the number up to 107. Four of these patients died, one as the result of the chloroform anesthesia, one through sepsis said to have been present before the operation, and two patients operated on by Baumm, though Gigli expressly disclaims all responsibility for these two, as he alleges that the innovations in technique introduced by Baumm seriously altered the nature of the procedure. Even admitting the mortality of 4 per cent., however, Gigli points with pride to the advance made since the days when the operation of symphyseotomy, devised by Sigault, which at the best has a mortality of 11 per cent., was heralded as a great step in advance.

Young as the operation is, it has already been made the subject of many modifications. Gigli's original recommendation was to make a skin incision, beginning at the mesial border of the pubic bone and running downward and slightly outward to the so-called subpubic tubercle. The Gigli wire saw was to be passed behind the bone from above downward by means of a suitable director under control of the fingers in the vagina, and the bone sawed through in the line of the skin incision. Other operators have changed the line of section somewhat, but perhaps the most important suggestion is that of Döderlein, who has transformed the procedure into a subcutaneous one by making only a small transverse incision over the spine of the pubis, through which, under the guidance of the vaginal fingers, a blunt curved needle is forced behind the bone and against the skin of the labium majus, which is slightly nicked with a knife to allow the instrument to emerge and draw the saw after it from above downward. Others advocate passing the saw from below upward, and special carriers, such as that of Seeligmann, have been devised. The recommendation to clear the way for the passage of the blunt director by burrowing through the tissues behind the bone with the finger, as Döderlein originally recommended, is discountenanced by many authors. Some operators have advised applying the saw as a prophylactic measure in cases in which it seems likely early in the labor that a material disproportion exists between the fetal head and the bony outlet. If section of the bone becomes necessary, at the proper moment a few to-and-fro movements of the hands suffice to effect the division, while if the birth can be effected without this aid, the saw is withdrawn and the patient will have suffered only two insignificant cutaneous incisions. Bauereisen believes it will be found advisable in many instances to allow the labor, if possible, to be terminated by the patient's own expulsive efforts, even if considerable time must elapse after the operation, but most authors empty the uterus immediately after division of the bone. The immediate dangers of the operation are said to be very slight, primary union is reported in nearly every instance, and hemorrhage is said to be easily controllable by pressure, especially if care has been taken to hug the bone closely in passing the saw, so as to minimize the injury to the cries of the clitoris. The bladder was wounded in one reported case, however, and the occurrence of hematomata is frequently noted in the case reports, though they do not seem to have caused complications of moment.

The advantages claimed for hebotomy over symphyseotomy are sufficiently great in the eyes of its advocates to entitle it to serious consideration in cases of contracted pelvic outlet. According to Stoeckel (*Berliner klinische Wochenschrift*, January 29, 1906) enough room is gained to permit the passage of a living child, even with a true conjugate of only 6.5 to 7 cm., and this is effected without incurring the immediate and remote dangers attending symphyseotomy. The latter operation is characterized as essentially unsurgical as it involves the division of a joint, and the concomitant great susceptibility to infection, while in pubiotomy secure repair is possible and the risk of injury to clitoris, urethra, or bladder is reduced to a minimum. The reported cases show that the patients do not experience any difficulties in walking after pubiotomy, and the after-treatment of the operation is very simple. Most operators content themselves with applying a very simple form of retentive dressing, such as a strap of adhesive plaster, while Bauereisen goes so far as to dispense with any effort to immobilize the sawn ends of the bone, and even encourages motion in order to secure fibrous union. This is rarer, he says, than bony union, but is advantageous as it favors an enlargement of the pelvis which would facilitate future deliveries. In two cases of his own and one of van der Velde's this increase amounted to as much as 1½ cm. in the true conjugate diameter.

It is still much too early to express an opinion as to the value of Gigli's operation. With but few exceptions the continental writers praise it, but the number of observations is still too small to permit of satisfactory estimate of its probable destiny in the annals of midwifery. In view of the modern tendency invariably to condemn perforation of the living child, in hospital cases at least, it is highly desirable not to neglect the development of any

method that may, as the friends of hebotomy claim for it, prove simple, safe, and effectual enough to enable the practitioner, cast on his own resources, to be reasonably sure of saving both maternal and fetal life when he is confronted by conditions which would otherwise place him in the dilemma of either performing cesarean section or resorting to the painful necessity of sacrificing the life of the child.

LIGHT AS A DISEASE PRODUCER.

Everyone is familiar with the phenomena of freckle, tan, and sunburn as the result of exposure to solar rays, especially in the summer season, and most physicians recognize the sun's influence in intensifying at least various forms of chloasma and pigment staining of the skin. The more serious effects of light in the production of cancer, however, have not received the attention the subject merits, and it is only now when the *x*-ray as a causative factor in carcinoma is attracting notice that the influence of ultraviolet and other rays is being investigated in this direction.

Charcot was probably the first to attribute the injurious effects of light on the skin to the chemical rays, and experiments with the actinic ray of the arc light in producing artificial summer hydroa by Möller and others confirm the belief that ultraviolet rays are at fault, and not the heat rays, as was thought prior to 1859. Besides the effect of light in causing erythema, lentigo, chloasma, pellagra, vernal hydroa, etc., and aggravating variola and perhaps a number of skin affections we have in xeroderma pigmentosum, a most interesting example of the influence of light in producing carcinoma. In Allen's "Radiotherapy" this pigmented epitheliomatosis of youth is said to assume a decided interest from the standpoints of cancer etiology and the pathology of skin changes produced by light. The onset is often noticed after exposure to strong light has produced a "sunburn," which disappears slowly to be succeeded by brown pigment spots. The prophylactic effect of excluding sunlight by thick veils worn by predisposed children has demonstrated clinically the injurious action of the rays. In what this author calls pseudoxeroderma pigmentosum there is in late life a pigmented, warty, telangiectatic, and atrophic state of the skin of the face accompanied by multiple epitheliomata in men who have spent much of their lives upon the water or exposed to the sun, and he believes that "the relatively great frequency of epithelioma upon the face may well be attributed, at least in part, to the irritative agency of chemical rays."

In a paper by James Nevins Hyde on "The Influence of Light in the Production of Cancer of the Skin" (*American Journal of the Medical Sciences*, January, 1906), the same view is taken and it is thought that the epithelium is stimulated by the inconceivably rapid velocities of the actinic rays to a proliferation beyond its physiological limits. The relative freedom of colored races (absolute absence of cancer in Tunis and rarity in Algiers) finds a natural explanation in the protection furnished by the colored skins. The conclusions reached by Dr. Hyde are: (1) The skin of the human body, in a certain proportion of individuals, and in those only, is hypersensitive to the action of the actinic rays of the spectrum. (2) This hypersensitiveness may be exhibited in the production of either hyperemia, pigmentation, telangiectasis, atrophy, hyperkeratosis, or cancerosis of the skin; or by all, at times in a determined order of succession. (3) In the form of childhood cancerosis known as xeroderma pigmentosum, the pigmentation, telangiectasis, atrophy, hyperkeratosis, and cancerosis of the skin resulting from exposure to rays of light are exhibited early in life, instances of this disorder being exceedingly rare. (4) Pigmentation, telangiectasis, atrophy, hyperkeratosis, and cancerosis of the skin occur in adults much more frequently than in childhood, reaction to the play of actinic rays of light upon the surface being chiefly determined after the middle periods of life have been reached. (5) Physiological pigmentation of the skin in the colored races seems to furnish relative immunity against cancerosis of that organ. (6) The colored races apparently suffer less than the whites from cancer of other organs than the skin. This relative immunity may be due to the protection from actinic rays of light furnished by the pigment of the integument.

It will be remembered that Loeffler, observing that cancer was infrequent in the tropics, where malaria was rife, offered the suggestion that there might be a natural antagonism in these two diseases which could possibly be turned to account therapeutically. Hyde's study would appear to show that the rarity of cancer in the tropics is due merely to the protection against the solar rays offered by the pigment in the dark-skinned races and has no relation whatever to the prevalence of malaria. The observation adds another argument to Woodruff's contention that blond men have no business in the tropics, and that if they go there to reside they do so at their peril.

As the theory of parasitism wanes it might be well for investigators to study the question of malignant growth rather more from the side offered by multiple cancer as it occurs in the presenile skin of youthful subjects of xeroderma.

The Nuisance of the River Noises.

The Health Commissioner of New York has taken measures to abate the smoke nuisance created by the North River craft which burn soft coal and emit clouds of soot which the westerly winds blow over the city. He will earn the thanks of his fellow citizens if he succeeds in reducing ever so little this insult to the town; but while his attention is directed to the offending tugboats he will do well to curb their even more pernicious activity in another direction. We have several times referred to the intolerable and sleep-destroying noise caused by the wanton shrieking of the sirens which many of these boats carry without necessity or reason. For some months one public-spirited woman, Mrs. Isaac L. Rice, has been carrying on, single-handed, a warfare against the noise-loving captains of these wretched little tugs. She has enlisted in the crusade the sympathy of the superintendents of the city hospitals along the river fronts, the Association of Masters, Mates, and Pilots (10,000 strong), the National, State, and Municipal authorities, the newspapers, and many thousands of the suffering citizens of this town—and the measly

tugboat captains keep on whistling. The agitation has not been wholly fruitless, for the whistling is a little less continuous than it was, but it is still much more frequent and much louder than there is any necessity for. A great step toward the abatement of the nuisance would be the substitution of ordinary whistles for the diabolical sirens. Rivermen aver that siren whistles are not only needless, but are an actual menace to navigation (as well as to health), because they render inaudible the signals from other boats. One important result of Mrs. Rice's crusade has been the placing of the responsibility for the continuance of this nuisance. She has obtained from the Federal authorities the specific declaration that the municipal and State officers alone have jurisdiction in the matter. It would seem, therefore, to rest with Dr. Darlington to abate this very serious evil, and we doubt not, now that his authority in the matter has been defined, that he will act with his usual energy and zeal for the health of the community.

A Proposed Seaside Park.

A BILL has been introduced into the State Legislature by Assemblyman Tompkins to create a commission for the purchase of a stretch of ocean front on Long Island and its conversion into a park and convalescent home. The bill is now in committee, but will come up for a hearing next week, when there should be a strong representation from the city to impress upon the up-State members of the Assembly the great need which exists for such a breathing place for the children of the poor and for convalescents. The project is one which has long been agitated, and has now received the powerful support of Mayor McClellan, who embodied a recommendation of it in his first message to the Board of Aldermen at the beginning of the year. "Provision must soon be made," he said, "by the city toward securing fresh-air homes for children and convalescent patients from the city hospitals, as well as breathing spaces for the whole people." He mentioned Long Beach, Rockaway Beach, and Coney Island as especially available for these purposes. Long Beach is the best of the three, but it has the disadvantage of being the farthest away, and is, moreover, outside of the city limits. Coney Island is the most accessible, but property there is very valuable and it is not likely that the appropriation of $2,500,000 provided for in Mr. Tompkins's bill would suffice for the purchase of the necessary waterfront and erection of buildings. Rockaway Beach would, therefore, seem to be the most suitable site for the park. It is said that a long stretch of beach can be purchased for about $1,000,000, leaving a balance of $1,500,000 from the appropriation for laying out the park and erecting the necessary buildings. This, however, will be a matter for the commission to decide, if the bill is passed. What is of present concern is the passage of the measure. New York City has many and extensive parks inland, but a town having so many miles of ocean front as this should have a public reservation free to all its citizens, where they could go to inhale the tonic and germ-free salt air. A convalescent home there would relieve the congestion of the city hospitals which now have to harbor many not yet well enough for discharge who fill the beds urgently needed for the acutely ill. These patients would, moreover, convalesce much more rapidly at the seaside than in the crowded hospital wards. In addition to the hearing on the Tompkins bill in Albany there will be a public hearing before the Board of Estimate in this city on March 9.

News of the Week.

Medical Society of the County of Kings.—At the eighty-fifth annual meeting of this society, held January 16, 1906, under the presidency of Dr. James W. Fleming, the following officers were elected for the ensuing year: *President*, William F. Campbell; *Vice-President*, Glentworth R. Butler; *Secretary*, John A. Lee; *Associate Secretary*, William A. Jewett; *Treasurer*, Onslow A. Gordon; *Associate Treasurer*, John R. Stivers; *Directing Librarian*, James P. Warbasse; *Censors*, Ralph H. Pomeroy, Henry G. Webster, John R. Kevin, William C. Woolsey, Julius Bierwirth; *Trustee*, James W. Fleming.

Centennial Celebration of the County Medical Society.—The dinner to celebrate the centennial of the incorporation of the Medical Society of the County of New York will be given at the hotel Astor, Times Square, on Wednesday, April 4, 1906, at 7 P.M. Members of the society are requested to notify at once the chairman of the Committee of Arrangements, Dr. Walter Lester Carr, 68 West Fifty-first Street, of their intention to be present. The price of the tickets is $6, and checks are to be made payable to Dr. Chas. H. Richardson, treasurer, 336 Lexington Avenue.

Harvey Society Lectures.—The eleventh lecture in the Harvey Society course will be delivered by Professor J. C. Webster of Rush Medical College, at the New York Academy of Medicine, on Saturday, March 3, at 8:30 P. M. Subject: "Modern Views Regarding Placentation." All interested are invited to attend.

The International Congress at Lisbon.—The opening exercises will take place on the first day of the Congress in the hall of the Geographical Society in the Geographical Society Building, where a colonial exposition will take place during the meeting of the Congress, under the auspices of the sections on colonial and naval medicine. The names of those who will deliver the general addresses have already been noted in the MEDICAL RECORD, with the exception of Dr. N. Senn of Chicago, who will deliver an address on the "International Investigation of Carcinoma." The amusements for the visitors will be a Portuguese bull fight, three large general fêtes, and several receptions and dinners. The hotel and other accommodations for the medical visitors are in the hands of Mr. Manuel Josida Silva, Redaction du Annuario Commercial de Portugal, Praca dos Restauradores, Palacia Foz, Lisbon, to whom all communications concerning board and lodging in Lisbon should be addressed. All communications regarding the scientific part of the Congress should be addressed to Dr. Ramon Guiteras, Secretary of the American National Committee, 75 West Fifty-fifth Street, New York, N. Y. All questions regarding transportation to Lisbon and return should be addressed to Dr. Charles Wood Fassett, Editor of the *Medical Herald*, St. Joseph, Mo.

Pure Food Bill Passed.—The so-called Pure Food Bill passed the Senate on February 21. The bill makes it unlawful for any person or corporation to manufacture, sell, offer for sale or deliver for shipment or to cause to delivered, shipped, or transported from any place within the jurisdiction of the United States any article of food, drugs, medicines, or liquors which is adulterated or misbranded, or which contains any poisonous or deleterious substance. The penalty provided is $500 fine or one year's imprisonment for the first offense, and $1,000 fine or imprisonment for each subsequent

offense. The second section extends the penalties to persons or corporations who offer to ship or receive for shipment either to any place within the United States or to any foreign country such articles. Drugs sold under a name recognized in the United States Pharmacopeia or National Formulary are required to be of the same standard of strength, quality, and purity as determined in the latest test, unless the standard of strength, quality, or purity is stated upon the label. In the matter of food product the bill forbids the mixing of any substance with it which reduces the quality of the article or is a substitute for it, or if any valuable constituent of the article has been abstracted it is then declared to be adulterated and contraband. The bill forbids the sale of a food article under the name of another article, the mixing, coloring, powdering, or staining of a food product to conceal its defects or the labeling of it to deceive the producer.

Amendment to the Illinois Pure Food Law.—The legislative body of the Chicago Medical Society has recommended a radical amendment to the Illinois Pure Food Law. The proposed amendment provides for transferring the duties of the Commission to the State Board of Health, putting all employees under the civil service, and providing that all chemical and bacteriological examinations of the Board, including the examination of food products, be made in the laboratory of the State University at Urbana. Having declared its position with reference to the State Food Commission, the Council of the Chicago Medical Society took further action, as follows: Specifically endorsed the bill to increase the efficiency of the Medical Department of the Army. Endorsed the Heyburn pure food bill, and all other measures advocated by the American Medical Association. Recommended the passage of a bill to control patent medicines, which shall provide that all medicines shall have a label stating the name and amount of all ingredients, and that all medicines containing opiates and similar drugs be marked with a poison label, with the understanding that the execution of this law should devolve on the State Board of Health, and that the Laboratory of the State University should be used in making the necessary examinations.

Sanitary Regulation of Cold Storage.—After seven months of persistent effort, the Commissioner's proposed ordinance for the sanitary regulation of the cold storage industry, has been favorably considered by the Committee to which it was referred by the City Council, and will be recommended for enactment. The vital provision of the proposed measure is that forbidding the sale of any slaughtered poultry, fish, game, or any animal used for food purposes, refrigerated or otherwise, which has not been properly drawn and prepared by removing the entrails at the time of slaughter. Other provisions of the Whalen Ordinance require cold storage warehouses to be in sanitary condition; regular inspections to guarantee this. An annual license fee of $500, the license to be issued only after strict compliance with the sanitary requirements. Every article to be tagged permanently to show the date it is put in storage. Retail grocers to exhibit storage meats in original packages from the warehouses, to show the age of the food and its history.

Tuberculosis Exhibition.—The tuberculosis exhibition, which the committee on the prevention of tuberculosis of the Charity Organization Society is sending about from place to place in the city, has now been installed at the Educational Alliance, East Broadway and Jefferson Street, where it was formally opened by the commissioner of charities, Robert W. Hebberd, Tuesday evening, of last week.

Donation to St. Luke's Hospital (Chicago).—One of the finest appointed hospitals in the country, where patients can receive the best medical treatment and high-class accommodations, is to be erected by the trustees of St. Luke's Hospital, as the result of the donation of $500,000, by James Henry Smith, of New York. In their annual report, the trustees have pointed out that hospital management in certain branches is conducting a hotel for the sick. It is reasonable that patients accustomed to a high class of accommodations when they are in good health would expect and be willing to pay for at least as good conditions when they are ill. The tendency has been for privacy and well-appointed rooms. The present endowment fund of the institution amounts to $313,000. It has surgical and medical wards, two wards for children containing twenty-four beds, a lying-in ward, and also those for eye and ear service.

Hospital Economics.—At a preliminary meeting of representatives of more than a score of hospitals held February 24, at the United Charities Building, with a view to effecting a permanent organization, having for its object stated conferences for comparing salaries and commodity prices. These officers were elected: *President*, the Rev. George F. Clover of St. Luke's Hospital; *Vice-President*, Mrs. B. M. Stimpson of the Infirmary for Women and Children; *Secretary*, Dr. S. S. Goldwater of the Mount Sinai Hospital; *Treasurer*, Amzi Lake of the Lincoln Hospital. Tentative schedules embodying details in hospital management and support, including salaries and cost of supplies. were distributed to the representatives. These are to be filled in, and from the returns so made permanent schedules will be systematically worked out at subsequent meetings. The next conference will be held within a month.

Football Through German Spectacles.—Prof. Wilhelm Ostwald of the University of Leipsic has returned to Leipsic after delivering his course of lectures at Harvard, and is preparing a report of what he observed for the Prussian Ministry of Education. In a newspaper article giving his impressions of American student life, he says: "The personal interest of the students next to their studies is concentrated alone on sport, which draws their attention altogether from intellectual or esthetic pursuits. Football before all is loved uncommonly, and it is practised in such a fashion that academic and State authority are near to forbidding it altogether. In the course of a single semester nineteen students fell victims to enraged brutal handling. At every American university is a sort of open amphitheater in which many thousands of spectators view the periodic football battles."

Civil Service Examinations for the State and County Service.—The State Civil Service Commission announces examinations to be held on March 17, 1906, for the following positions: Dentist, State Charitable Institutions, fees not exceeding $40 a month; Nurse, Monroe County Hospital, $240 to $300 and maintenance; Orderly, Monroe County Hospital, $360 and maintenance; Physician, Sixth Grade, $900 and maintenance. The last day for filing applications is March 12. Application forms and detailed information may be obtained by addressing the Chief Examiner of the Commission at Albany.

The Linnæan Society of New York.—Dr. Robert T. Morris will deliver a lecture under the auspices of this society on March 14, at 8.15 P.M. in the large lecture room of the American Museum of Natural History, entitled, "A Naturalist's Camping Trip to Hudson Bay."

Quarantines at Gulf Ports.—A movement is on foot among the railroad, steamship, and commercial interests at Havana to secure the good offices of the Government at Washington against the threatened quarantines at Gulf ports. President Palma is urging the Cuban Congressional leaders to press the pending appropriations for sanitation so as to leave no ground for criticism.

Health Commissioner for Brooklyn.—An appeal has been made by the King's County Medical Society to the president of the borough of Brooklyn to have a bill proposed providing for the appointment of a separate health commissioner for Brooklyn, instead of an assistant sanitary superintendent, as at present. The society contends that the Health Department of the borough cannot be administered with satisfaction either to the medical profession or the public because of lack of authority and direct responsibility.

Photographing Bacteria.—It is reported from Boston that Professor H. C. Ernst of the Harvard Medical School has devised a new method of photographing unstained bacteria by means of ultra-violet rays.

Smallpox.—A smallpox epidemic of some importance has broken out in the neighborhood of Owensboro, Ky., and the local authorities are said to be having much difficulty in enforcing quarantine regulations. There is also much popular opposition to vaccination, and the district is being flooded with antivaccination circulars.

Sixth Councillor District Medical Society of Ohio.—At the meeting of this society, held at Akron on February 13, the following officers were elected: *President*, Dr. A. B. Walker of Canton; *Secretary*, Dr. J. H. Seiler of Akron; *Treasurer*, Dr. H. H. Jacobs of Akron; *Councillor*, Dr. T. Clarke Miller of Massillon. It was decided to hold the August session at Orrville.

Taliaferro County (Ga.) Medical Society.—This society was organized on February 8, with the following officers: *President*, Dr. A. C. Davison, Sharon; *Vice-President*, Dr. J. A. Rhodes, Crawfordville; *Secretary and Treasurer*, Dr. Alex H. Beazley, Crawfordville.

Obituary Notes.—Dr. CHARLES MCDONALD of New York died on February 21, of heart disease, at the age of eighty-one years. He served through the Civil War in the Confederate Army.

Dr. H. MARTYN GRACE of Perth Amboy died on February 20, after an illness of several months. He was born in 1859 at Catskill, N. Y., and went to Perth Amboy from Port Jervis in 1892. He was prominent in public life and at the time of his death was Mayor of Perth Amboy.

Dr. THOMAS ROSS of Sacramento, Cal., died on February 11, as the result of a paralytic stroke. Dr. Ross was a native of Lancaster, Ont., where he was born in 1840. He was graduated from McGill University, Montreal, in 1863. In 1870 he located in Woodland, Cal., and in 1893 removed to Sacramento. He had occupied many public positions and at different times was superintendent of the Southern Pacific Railroad Hospital, secretary and then president of the State Medical Society, and at the time of his death was president of the Sacramento City Board of Health.

Dr. WESLEY DAVIS of Worcester, Mass., died on February 17, of paralysis, at the age of sixty-five years. He received his education in the University of Vermont and in the Berkshire Medical School. During the Civil War he did service on the hospital staff of the army of the Potomac, although he was not an enlisted physician. At the close of the war he went to Worcester and continued practising there till the time of his death.

Dr. WARREN P. BLAKE of Springfield, Mass., died on February 15, at the age of forty-eight years. He received his medical diploma from Dartmouth College in 1884 and practised in Farmington, N. H., until 1893, when he went to Springfield.

Dr. WILLIAM BARBER of Waverly, Iowa, died on February 12, at the age of seventy-six years. He was a graduate of the Medical Department of the University of Michigan and had practised in Waverly since 1879.

Dr. O. W. WOODS of Roanoke, Va., died on February 13, of tuberculosis, at the age of thirty-five years. He was graduated from the medical department of the University of Virginia in 1893, and after serving in the Spanish-American War he went to the Philippines as contract surgeon in the United States Army. He was later made assistant surgeon in the regular service, and on his return from the Philippines served at several posts in this country.

Dr. ELISHA H. GREGORY of St. Louis died on February 11, at Ormond, Fla., after a long illness, at the age of eighty-two years. Dr. Gregory was born in Kentucky but went to St. Louis in 1848, and almost immediately became prominent in medical circles. For more than half a century he held the chair of Surgery and Anatomy in the St. Louis Medical College, and he also served on the board of Health of St. Louis as president of the State Board of Health of Missouri, was twice president of the St. Louis Medical Society, and was president of the Missouri State Medical Association. In 1886 he was elected president of the American Medical Association.

Dr. LAIRD N. WOODS of Dallas, Or., died on February 13, of septicemia, at the age of seventy-one years. He was born in Greenville, Pa., and received his medical education at the Buffalo Medical College. He went to Oregon in 1883 and had practised in Dallas ever since. He was coroner of Polk County several times and was a member of the Board of Pension Examiners for many years.

Dr. GEORGE L. NEWCOMB of Scituate, Mass., died on February 21, after a long illness, at the age of seventy-four years. He served as surgeon in the Civil War and then practised for some years in St. Albans, Mass., before removing to Scituate.

Dr. HAROLD F. THOMPSON of Worcester, Mass., died of pneumonia on February 19, at the age of twenty-five years. He received his medical degree at Tufts' Medical College and at the time of his death was serving as interne in the Worcester City Hospital.

Dr. ANDREW M. MILLER of Detroit died on February 16, as the result of a stomach affection of long duration. He was graduated from the medical department of the University of Michigan in 1888, and before going to Detroit in 1899 had practised for several years in Alpena, Mich., where he served as health officer and in other positions.

Dr. THOMAS KELLEY died at his home in San Jose, Cal., on February 14, at the age of seventy years. He was a native of Clinton, O., took his degree at Rush Medical College, Chicago, in 1871, and settled in California in 1876.

Correspondence.

CELLULOID PLATES FOR CRANIAL DEFECTS.

To the Editor of the Medical Record:

Sir:—The insertion of celluloid plates to fill depressions due to loss of portions of the skull may be sufficiently rare to justify a report of the result in a case of this character, in which the operation was done in 1904. The patient had received a bullet wound in the forehead, near the normal limit of the hair and to the right of the frontal sinus. Loss of substance was complete and entailed a depression almost circular in shape, about an inch in diameter, and deep enough to produce a marked disfigurement. I inserted a series of sterile celluloid plates, which filled out the depression. A letter just received from the patient and his physician, two years after the operation, informs me that the plates have remained in position, and have been perfectly satisfactory in giving protection to the brain over the exposed area and in doing away with the disfigurement.

John A. Wyeth, M.D.

OUR LONDON LETTER.

(From Our Special Correspondent.)

SIR J. TUKE'S SUCCESS—MEDICAL CANDIDATES—TRAUMATIC PARAPLEGIA—TETANY—MYELITIS OR PERIPHERAL NEURITIS? TUBERCULOSIS; MARAGLIANO'S SERUM AND BEHRING'S NEW PREPARATION — SANITARY INSPECTORS — MILITARY NURSE'S FUNERAL—THE FEEBLE-MINDED—DEATH OF DR. PURDON.

London, February 9, 1906.

The penultimate parliamentary election was completed yesterday and the poll was announced last night. The graduates of Edinburgh and St. Andrews have given a sweeping majority of more than 2 to 1 to the medical candidate—Sir J. Batty Tuke, who was their member in the last parliament. The numbers were 4,893 for Sir J. B. Tuke, against 2,310 for his opponent, Mr. Strachey, who was not a medical man, not a graduate of any university, and who rested his claim on being a thorough free trader, and on having, in his own opinion, done much, as the editor of the *Spectator*, to save the empire from ruin through protection. There are several points of interest about this election. Many looked forward to it with a certain degree of curiosity as to whether it would reverse its former record. The last previous contest was in 1885, when a conservative was returned by a majority of 387. In 1900 Sir J. Tuke was unopposed. The appearance of an opponent was resented by some, but all seems to be fair in politics, and as the liberals thought that a free trader would assist them they supported the "interloper." Others were curious to see whether the Scotch universities would continue to vote as do the English, and so show that the educated constituencies are conservative as a whole, but by no means afraid to look change in the face, and are well aware that the condition of the country is now quite unlike it was sixty years ago. Another curious point, but equally noticeable in many other contests, is that liberals and radicals who have generally been advocates of reforms and change have suddenly become the most conservative opponents of any fiscal changes.

Again this contest is noteworthy from a professional point of view, as we have long been lamenting the absence or weakness of medical and sanitary representatives in parliament, and most of us have advocated a determination to support medical candidates wherever found. But here when an able candidate who had served the profession well in the last parliament was opposed, a number of medical men deserted their old representative and raised a cry on the impropriety of setting class against class and the danger of changing a system which had lasted sixty years. Really their logic seems as obscure as their casuistry.

A case of chronic tetany cured by thyroid treatment was shown at the Clinical Society on the 28th ult. The patient was a girl aged 9, who for eighteen months had been unable to walk, and the abdomen had become much distended during these months. For seven months there had been repeated attacks of tetany; anemia became marked; face puffy with edema of hands and feet. The knee-jerks had at one time been lost, but returned, and the tetany had disappeared under salol. This now failed, but the knee-jerks were still absent. Thyroid substance was given for a week, and the attacks of tetany disappeared and have not returned. Treatment was lately resumed on account of pains in the feet when walking or standing.

Dr. A. E. Garrod referred to a case he had last year brought before the society in which the patient had been repeatedly relieved by lavage, and at the post mortem the sigmoid flexure was found greatly hypertrophied.

Dr. Batty Shaw thought a toxin was formed somewhere which overwhelmed the nerve centers.

The president, Mr. Clutton, remarked that if the trouble was in the sigmoid the case should be operated on.

A case of laminectomy for traumatic paraplegia in a man of 36 was exhibited. The injury caused loss of motion and sensation of the legs, loss of knee-jerks, and plantar reflexes with incontinence of urine and feces. The arches of the first and second lumbar vertebræ were found, on operating, fractured and depressed so as to compress and injure the nerve structures. Sensation returned twenty-four hours after operation in the right leg; a little later in the left. The functions of the rectum and bladder were restored in three weeks and the power of movement gradually restored, so that the patient can now walk without assistance. The injury occurred last October. The knee-jerks remain feeble and the plantar reflexes absent.

Mr. Clutton observed that the recovery was noteworthy, as absence of knee-jerks and reflexes were usually considered contraindications for operating.

Dr. C. E. Beevor said the injury to lumbar nerve roots of the third and fourth vertebræ would account for absence of the knee-jerks in this case and so not contraindicate operation; but injury high up would, as it showed damage to the anterior horns.

There was also shown a case of recovery from what was supposed to be transverse myelitis in a man of twenty-nine who was seized nine days before admission with pains in the legs and back, weakness of the arms coming on and loss of control of the sphincters. Loss of power and sensation in the legs followed, then paralysis of intercostals and diaphragm. Anesthesia spread upwards to the nipples. He improved gradually and after nine months could walk without assistance. The knee-jerks returned after an absence of six months.

Dr. C. E. Beevor could not see how a man could breathe with persistence of paralysis of the diaphragm indicating the lesion to be as high as the fourth cervical vertebra. He suggested that possibly the case was one of peripheral neuritis of all four limbs.

Some interest has been revived in Maragliano's serum in consequence of a statement widely distributed that much improvement has been effected in it. It is said that Dr. Maragliano considers it is now perfect and that the Genoa Anti-tuberculosis Institute can supply the product in quantity. An interview with Professor Bouchard of Paris, has appeared in some of the newspapers in which he said the first patient on whim he tried it was cured but in some later cases he had been less successful. He warned the interviewer against prematurely raising hopes which might not be realized.

Some account of a statement made yesterday by Prof. v. Behring at Berlin has been telegraphed to us. Referring to his "T. C." preparation he is reported to have improved it—in fact so changed it as to rename it. Now he calls it "tuberculase" and has treated with it cows which were free from symptoms and appeared to be sound but which gave milk containing virulent tubercle bacilli. In a few weeks the bacilli disappeared under the treatment. He hoped it might be possible to prevent human tuberculosis but it was not to be supposed it could cure developed consumption. Prof. v. Behring reiterated his determination not to supply his preparation for use on human beings before next autumn and therefore it was useless for medical men to ask him to make exception on behalf of their patients.

The Sanitary Inspectors' Association had their annual dinner on Saturday, when the past chairman was presented with a gold watch and his wife with a gold bracelet. A prize of fifty guineas and the Chadwick gold medal for the best essay was presented to Mr. Jas Lord of Failsworth. Sir W. Broadbent proposed the toast of "Science and Art" and hoped the inspectors would wage as successful a war against tuberculosis as they had against fever and other diseases. Sir Wyke Bayliss responding said art and sanitation were not so far apart. One of the loveliest things in the world was a drain (laughter) when it was consecrated by art in the form of a gargoyle on the roof of a cathedral. Art was the science of beauty, sanitation was the science of health. Beauty and health were the same. The President of the Association, Sir J. Crichton-Browne, suggested that when an epidemic occurred in a town the local authorities should be made to march out with halters around their necks and hand over their duties to a government inspector for a time. The inspectors seem to have had a good time.

The Institute of Hygiene is organizing popular lectures. Dr. C. N. Meachen gave one this week on "The Ear and Hearing." He said an organ for hearing appeared early on the stage of evolution and when man came on the stage he

showed retrogression. This statement he explained by the fact that man does not prick his ears though he may perhaps reacquire the faculty and he has a rudimentary mechanism still. After this popular homage to the doctrine of evolution he gave some good advice to his audience on the danger of meddling with their ears with hair-pins, boxing the ears of children, etc.

At an official inquiry into a rehousing scheme proposed by a railway company which is displacing nearly 1,000 tenants in Kensington, the Borough Council objected that no one-room tenements were provided—only two, three and four roomed. The Medical Officer of Health, it was said, agreed with the Council that one-roomed tenements should be arranged for as in some cases they were necessary and forty-one tenants of this class would be displaced by the demolition of their homes.

Miss Fitzgerald of the Queens Nursing Service, who died at Aldershot while acting as military nurse, was buried on Tuesday in the Military Cemetery with military honors. Six members of the R. A. M. C. acted as pall-bearers and the band of the corps headed the procession, playing funeral marches. The chief mourners were followed by detachments of sisters from the various military hospitals and after them a company of the R. A. M. C. with General Macnamara and other officers in the rear. The funeral is described as unprecedented and unparalleled.

Brompton Hospital authorities contemplate an extension of its scope in the direction of dealing with tuberculosis from a national rather than an individual aspect. A subcommittee representing the staff and managers has been appointed, and Dr. Newsholme will be consulted on such matters as his great experience in sanitary matters may be supposed to assist in the deliberations, more particularly, perhaps, as to the sources of infection in the homes of the poor, as the object of the inquiry is not so much the efficient treatment of the individual, which is the concern of the staff, but the discovery of other members of his family who may be affected. By active cooperation with medical officers of health it is hoped to reach each focus of infection, and so do something to lessen the incidence of the disease.

Dr. Nathan Raw, who has had some eighteen years' experience as a resident in asylums and hospitals, gave evidence before the commission on the feeble-minded. He thinks those defective children who are capable of benefit by instruction should be under the control of the local educational authorities, and those who are incapable of such benefit should be cared for by the county councils, either in special institutions or the county asylums. They should certainly be removed from workhouses.

Dr. Thomas Jackson held that counties or combined union districts should have "work schools" where improvable cases should be taught trades specially useful to such persons, and where attendants, nurses, and itinerant teachers could be trained.

Mr. T. Thompson, trainer to the Colchester Asylum, after fifteen years' experience of training boys, said the best plan was to teach them garden work, so that they could produce enough to live on. Government farms for 200 patients, in four homes of fifty each, would admit of classification, and would supply vegetables to the unions.

I regret to record the death, on the 21st inst., of Dr. H. S. Purdon, in his 61st year. He was consulting physician to the Skin Hospital and the Consumption Hospital in Belfast, where he enjoyed a high position among his professional brethren. He took the M.D., Glasgow, in 1865. His favorite subject was skin diseases, on which he published many papers, as well as the *Quarterly Journal*, on the subject, which he established and carried on for several years. The name of Purdon is closely associated with Belfast, members of the family having long been in practice there. His father and brother were Belfast physicians, and one of his two sons remains in the city, the other having crossed the Atlantic.

THE OSTEOPATHY BILL IN THE NEW YORK LEGISLATURE.

To the Editor of the Medical Record:

Sir:—The attention of the Medical Profession in this State is called to a bill introduced in the Legislature by Senator Hinman, entitled, "An Act Regulating the Practice of Osteopathy in the State of New York." This bill grants to certain persons permission to treat all diseases of the human body by the so-called osteopathic method, and exempts them from the educational qualifications demanded by the act, governing the right to practise medicine in this State. Section 6 of this bill states that "Any person who at the time of the passage of this act shall be actually engaged in the practice of Osteopathy in this State, and who is a graduate in good standing of a regularly conducted school of Osteopathy within the United States requiring a course of two years or longer, with actual attendance of at least twenty months, and who shall be recommended to the Regents by the State Board of Osteopathic Examiners, shall upon application and payment of twenty-five dollars ($25.00), *without examination*, be granted a license to practice Osteopathy, provided application for such license be made within six months after the passage of this act." Osteopathy as defined in the bill means "That science or system of healing which treats diseases of the human body by manual therapeutics for the stimulation of the remedial forces within the body itself, for the correction of misplaced tissue, and the removal of obstructions or interferences with the fluids of the body, all without the internal administration of drugs or medicines."

Osteopathy is a system of manual or hand therapeutics, and is a single agent used in the treatment of disease; as such, it has no greater claim to be separated from the general practice of medicine than electricity or electropathy, bathing or hydropathy, massage or kinesipathy, the *x*-ray or radiopathy, and mental science or psychopathy, and is not entitled to a special examining board. The eye, ear, nose, throat, electrotherapeutic, psychopathic, and other specialists do not ask exemption from the examination in the general science of medicine demanded by the regents of the University of the State of New York of all candidates who apply for a license to practise medicine or any branch of medicine, and they do not ask for an examining board in their specialty. If the osteopaths desire to establish a special branch of medicine, then they too should possess at least that average of the knowledge of preventive medicine, which is needed properly to control the spread of contagious and infectious diseases, and which is included in the general science of medicine demanded by the present law; and they should not try to escape, under the section quoted, the preliminary and final examinations for a license to treat the diseases of the human body.

The public has so long suffered from poorly educated physicians that every State in the Union has enacted laws raising the educational qualifications of the candidates to be examined for a license to practise medicine. The medical laws of the State of New York were enacted to protect the people of the State from charlatans, quacks, and pretenders of all sorts. The four years spent in the study of medicine prepares the mind and molds the character along the lines of truth and science and away from commercialism in medicine. A reaction from commercialism in medicine, and the tendency of modern times to raise rather than lower the educational standard of professional men, were factors in causing the Legislature to enact the laws which prevent any person, not presenting the intellectual and moral qualifications required by the law, from practising medicine "or treating the diseases of the human body" in this State. The public is protected by discouraging commercialism in medicine and is benefited by fostering the science of medicine, and not the least of the duties of physicians is the guarding of individual and public health along the lines of sanitation and preventive medicine.

To summarize the objections to the Osteopathic Bill:

First: The bill permits certain practitioners of a branch of medicine known as osteopathy to receive a license to practise legally a branch of medicine without passing an examination, there being no evidence that they possess any knowledge of sanitation and the protection of the public from contagious and infectious diseases.

Second: Osteopathy is a single agent or method used in the treatment of disease, and is included in the general practice of medicine, and is now and has been used by the licensed physicians of this State, and it should not have a special examining board, which would lower the educational standing of the physicians in this State.

Third: Osteopathy should not be made a special branch of medicine by an act of the Legislature, but should come under the present State laws, which govern all the special branches as well as the general practice of medicine. Any of the 11,923 licensed physicians in this State have already the right to practise osteopathy as a specialty.

Fourth: The Legislature should protect the public by withholding the endorsement of the State from any person, as being capable of treating the diseases of the human body, unless such person can make a diagnosis of the condition of the human body, and can protect the individual and the public from contagious and infectious diseases, to do which requires a full knowledge of the science of medicine as taught in the medical colleges of this State, including the use of drugs, sera, and other valuable therapeutic agents. From an educational standpoint the enactment of the Osteopathic Bill would be a retrograde movement, there being no recognized osteopathic college in this State.

And, finally, it would be more reasonable for the Legislature to separate the special branches of criminal, corporation, and real estate law from the general practice of law,

and establish for each of them a special examining board, than it would be for the Legislature to select one special therapeutic agent used in the treatment of disease and separate it from the general practice of medicine at the request of those enthusiasts who are now asking for a special osteopathic examining board.

The members of the Senate and Assembly should be petitioned, in the interest of individual and public health and to safeguard the educational standards of the State, to defeat "Senator Hinman's Osteopathic Bill, No. 293."

E. Elliot Harris, M.D.

Progress of Medical Science.

Boston Medical and Surgical Journal, February 22, 1906.

The "Home Sanatorium" Treatment of Consumption.—J. H. Pratt reminds us that the essential feature of the sanatorium treatment is careful regulation of the details of the daily life, and the essential feature of the climatic treatment is life in the open air. He has endeavored to carry out the same regulations in the homes of the poor in a crowded city. In an interesting paper illustrated with several photographs he gives the results of his experience. The difference between his methods and those of the usual tuberculosis dispensary is that while the latter gives a small amount of care to a large number of patients, he gives a large amount of care to a small number. He has organized a "tuberculosis class" in one of the churches in Boston which finances the plan. Each detail of the daily life of the patient is supervised, and strict discipline is maintained. A nurse devotes her time to visiting the class members. These are not accepted until either tuberculin or sputum examination has established the clinical diagnosis. Admission has not been restricted to incipient cases only. Before admission each applicant must promise to give up all work, live the out-door life and obey all the rules. Details of the treatment are given in the paper. Once a week the class holds a meeting. A nominal fee of two dollars per month is required. The class numbers now fifteen. The total expenses for the first half-year were a little over five hundred dollars. The plan outlined by Dr. Pratt is feasible in any community. Of nine patients who have been members of the class for three months or more eight show a gain in weight. In five the disease has been arrested. We commend this paper to all interested in the tuberculosis problem.

New York Medical Journal, February 7, 1906.

Diagnosis of Chronic Urethral Discharges.—S. L. Gans calls attention to the compressor urethra muscle as dividing the urethra into an anterior and posterior portion, and speaks of the periurethral glands, Cowper's glands, the prostate, and seminal vesicles as the urethral accessory sinuses. He advocates the use of the familiar two-glass test, and discusses the relative significance of the various deposits commonly found therein. He then discusses the various intra- and extraurethral lesions, going into considerable detail as regards clinical methods. Nothing essentially new is presented, but the paper, as a whole, is an excellent summary of the technic followed in the modern treatment of chronic urethritis. Concerning the endoscope, he says that he considers it a useful thing only in a comparatively few selected cases, and in hands thoroughly trained in its use. Under such conditions he regards it as a valuable adjunct, but under other circumstances a dangerous plaything.

Rheumatic Manifestations in Childhood.—E. J. McDonough enumerates under this category, growing pains, tonsillitis, chorea, endocarditis, pleuritic pains, torticollis, fibrous nodules, and anemia. The treatment he recommends may be summarized as follows: (1) Flannels the year round; (2) iron and cod-liver oil for the anemia; (3) for some time after an attack, salophen; (4) starches and sugars are restricted; (5) immediate treatment when any of the foregoing lesions appear, especially if there be a rheumatic diathesis; (6) removal of tonsils, adenoids, etc., as the infecting material commonly enters the system by this route; (7) sodium salicylate during acute attacks, wrapping the joint in cotton or splinting it if necessary.

Oxaluria.—H. H. Roberts alludes to an "alimentary" oxaluria which may come on after the ingestion of certain fruits and vegetables, such as asparagus, spinach, rhubarb, tomatoes, apples, grapes, lemons, turnips, onions, strawberries, also tea. Neither this form nor systemic oxaluria can exist without some disorder of metabolism. Stomach or intestinal disturbances are the most common. Hyperchlorhydria is frequently present, also nervous indigestion, flatulence, sour and bitter eructations. These patients are intensely irritable; they frequently have cold and clammy hands and feet; any unusual amount of muscular exercise produces undue muscular soreness; they suffer with neuralgia; they have muscular stiffness if they remain in any one position too long; lumbago is often a result; they have irritable hearts; they suffer with repeated attacks of insomnia, frequent and severe migraine, and frequent and sudden attacks of coryza. The author believes that oxalic acid is one of the congeners of uric acid. Mere examination of the amount of crystalline deposit in a given specimen of urine gives no accurate estimate of the amount really in the system. We must quantitatively examine a twenty-four hours' specimen. Roberts considers intestinal oxaluria to be one of the chief causes of appendicitis, colitis, etc. For general treatment he advises foods which are not oxalic acid producers, which increase combustion, and undergo easy oxidation. The alkalies and salicylates are the most valuable drugs. In addition, general hygienic measures, especially fresh air and well-regulated exercise, are called for.

Tapeworm Simulating Appendicitis Recurrens.—The patient of A. A. Gumbines was a woman of thirty-two years, with a three-years' history of pain in the lower right abdomen and occasional vomiting. A diagnosis of appendicitis recurrens was made and concurred in by three other physicians. A fourth claimed the condition was gallstones. The patient was not willing to submit to operation. Soon after she passed a tapeworm, since which she has had no further abdominal symptoms.

American Medicine, February 24, 1906.

A Case of "Neurasthenia," as Treated by Two General Physicians, One Homeopathist, One Quack, One Osteopath, Three Ophthalmic Surgeons, Two Gynecologists, One Diagnostician, One Neurologist, One Resident Sanatorium Physician, and One Refractionist.—George M. Gould reports the case of a woman, the wife of a physician, whose illness was said to date from the age of twelve, when she "jumped from a box." The symptoms were recurring "attacks of exhaustion" and other nervous phenomena, generally ascribed to a retroverted or twisted uterus by her physicians. Advice was obtained from the physicians mentioned in the title, many of whom were of the highest professional reputation. Slight temporary relief was obtained from two irregulars, none from the others. Pregnancy in 1903 cured the retroversion, but none of the symptoms. In 1904 incorrect glasses increased the intensity of the old symptoms and added new ones, still harder to bear. In 1905 correct spectacles at once brought about a cure.

Relation of Acid Fermentation in the Stomach to Neurasthenia.—J. Wirt Robinson does not believe that the statements usually made that the nerves are in a condition of under-nourishment in neurasthenia are true. It has been shown that if the amount of oxalic acid eliminated daily is much increased, symptoms of irritability appear. A small amount of oxalic acid is taken in with the food, but an excessive amount is due to an acid fermentation in the stomach. When excessive amounts of oxalic acid are absorbed (probably as the sodium salt, the nerves, with other tissues, have to suffer a loss of calcium, which has a strong affinity for oxalic acid. This produces a disturbed ratio of salts in nerve tissues, resulting in increased irritability. In regard to treatment, diet and hygiene stand first. Fermentable foods, as sweets and possibly starchy foods, must be restricted. The use of lime water furnishes calcium in the alimentary canal to unite with the oxalic acid and saves the vital tissues.

Bacillus Chlorhydrici.—E. Palier describes in detail, under this name, a new microbe, which he isolated from the human stomach and cultivated. It may be found in hyperchlorhydria and in chlorhydria, but not in hypochlorhydria, and hence its name. It is a small, slender, motile, Gram negative bacillus, and is aërobic. Its isolation is very difficult. *B. chlorhydrici* and yeast are the two germs usually found in hyperchlorhydria and in chlorhydria when the HCl is above 0.1 per cent., and they help the digestion of proteids and fats. Under abnormal conditions, when there is an abrasion or injury of the mucous membrane of the stomach, these two microorganisms may be the cause of round ulcer of the stomach, as they cause such an ulcer when rubbed into the root of the tail of a mouse.

The Sanatorium Treatment of Tuberculosis.—George B. Kalb says sanatorium treatment gives the best results because the patient is under continuous control, and nothing is left to the feelings or whims of the patient or his family. The total eradication of pulmonary tuberculosis is within the range of the possible, and to make

it more probable, institutions of three kinds should be established: (1) For incipient cases where practically all can be cured; (2) for advanced cases where a goodly percentage can be cured; (3) for far-advanced cases, where some can have their disease arrested and the path to the grave can be rendered less painful, while all can be prevented from infecting others.

Journal of the American Medical Association, February 24, 1906.

The Physiological Status of the Fetus in Utero.—W. H. Sanders holds that the beginning of life should be dated at conception and not at birth, as is now commonly done. The individual has an independent existence from the moment of union of the male and female germs; the mother is its temporary hostess. He states his views in the following propositions, which are submitted to the profession. "1. The conjunction of male and female germs constitutes, from a scientific standpoint, birth. 2. The term conception should be abolished and that of birth substituted therefor. 3. In dealing with all stages of pregnancy, even the earliest, physicians should recognize the extreme gravity of the condition, and should never condemn to death a fetus, however young, without the maturest consideration, and without calling to their aid the highest professional authority within reach; in a word, without carrying the case to the nearest and wisest medical supreme court accessible. 4. The principles herein contended for should be impressed on the members of the profession, taught to medical students and promulgated widely among the people. 5. Medical men should interest themselves to see that the statutes of their respective states are ample for the protection of the fetus *in utero*."

Metabolism in Cancer.—After summarizing the previous work in this line, H. H. Glosser and W. S. Frisbie report the results of their own studies to determine the relations of the nitrogen loss, if any, with the gain and loss of weight of cancer patients, as compared with normal individuals; to determine the possible retention of chlorides in the system, and its extent; to determine whether or not such retained chloride has any direct relationship with the supposed increase of chloride in the blood, and with the formation of edematous deposits; and to note the effect of adding or excluding chloride from the diet in cancer patients as compared with normal individuals. They found that in a normal individual, proteid starvation was followed by a loss of nitrogen, while the chloride equilibrium was maintained. In cancer patients the nitrogen loss showed considerable variations, explainable to some extent by other factors than the existence of the tumor. On the other hand, while a healthy person could assimilate enormous quantities of chloride and strike a balance in from twenty-four to forty-eight hours, cancer patients showed edema when chloride consumption was increased, the kidneys being unable to excrete the excess. The work shows the existence to some extent of toxic substances (not perhaps specific cancer poisons) in the system capable of interfering more or less with nutrition. They may be suboxidized nitrogenous products

Congenital Coxa Vara.—H. D. Feiss reports a case occurring in a child three years old, the evidence in which he thinks is sufficient to prove its congenital origin The extreme adducted position and the extreme flexibility noticed right after birth point to its intrauterine origin. He reviews the literature of the subject and reports experiments made with an eight-months' fetus hardened in formalin to demonstrate the mechanism of the deformity. He states his conclusions as follows: "Congenital coxa vara is usually associated with defects or deformities of other parts, commonly with defect of the femur and with deformities of the lower limbs. It may be intrauterine in its strictest sense; it may be the result of an intrauterine infection, or it may be combined with congenital rachitic deformities. At least some of the strictly intrauterine cases are associated with peculiar positions of the thighs in utero; that is, adduction of the thigh in question. This peculiar position of the joint might explain a fixed deformity in the later developing hip joint, if we may assume that the proximal end retains its relative position to the acetabulum after birth."

Endothelial Tumors.—F. R. Zeit remarks on the confusion that exists in the nomenclature and diagnosis of endothelial tumors, and points out the need of a better system. A correct diagnosis is of the greatest practical value since these tumors are slower in growth than other malignant growths and do not produce metastases or involve neighboring lymph nodes as early, hence the prognosis after thorough removal is better than with carcinoma or sarcoma. He gives the reasons for accepting endothelial tumors as a special class by themselves, and points out the biological and morphological differences between them and carcinoma and sarcoma. The general morphological characteristics of endothelioma distinguishing it from carcinoma are stated: the intimate connection of the cells with the stroma, the intercellular cement substance, the fibrillary processes, the arrangement of the cells, etc., also the organoid as distinguished from the histoid structure of sarcoma. Cases are reported illustrating the special morphological characteristics of the various types of endothelial tumors, according as the endothelial proliferation originates from lymph vessels or spaces, or from the outer or inner endothelial lining of the blood-vessels. Other endothelial tumors, such as cylindroma, resulting from hyaline metamorphosis of the vessel wall and psammoma and cholesteatoma, usually classified under this head, are briefly mentioned, but not discussed. The article is fully illustrated.

Sheet Paraffin in Eye and Nose Lesions.—E Moraweck and G. C. Hall recommend the use of splints made of dentist's sheet paraffin in nasal surgery to prevent adhesions, etc. The paraffin can be cut to suit the needs of the case, and if handled with clean hands and shaped with clean instruments and with the additional precaution of scraping it just before introduction, they have not found it necessary to keep it in irritating antiseptic solutions before using. They find the splints much better for preventing adhesions than either the gauze tampon or the Bernay splint, besides being less painful and inconvenient. Details are given as to their use in cautery operations, after submucous resection of the septum, after turbinectomy and in septal deformities, spurs, and ridges. The authors do not invariably use these splints in nasal work, but probably in about 50 per cent. of their cases. In eye work they have used the material in only one class of cases, in extensive lesions of the conjunctiva in which adhesions are threatened, or after operations for symblepharon. A piece is shaved to about half its original thickness, molded over an artificial eye, a circle is cut out in the center so that it does not encroach on the cornea, and it is then inserted into the conjunctival sac and left there as long as necessary. It is well tolerated, permits cleansing and after-treatment. This use of paraffin, the authors think, is original with them. The article is illustrated.

The Lancet, February 10, 1906.

Bilharzia Infection of the Vermiform Appendix.—J. Burfield and E. H. Shaw have been unable to find any records of a similar case to their own, which occurred in a man of thirty-six years, living in South Africa. He had had several gluteal and lumbar abscesses, and his symptoms finally justified an exploration of the appendical region, which was made by anterior abdominal incision in the usual way. Dense adhesions were found and a fluctuating swelling was found behind the pelvic peritoneum near the sciatic notch. The anterior wound was closed and a coexisting abscess in the right buttock was opened and found to communicate with the post-peritoneal swelling. All these cavities were drained, but the resulting sinus persisted and later the appendix region was again explored. The proximal end of the appendix was found very firmly adherent to the posterior pelvic wall near the sciatic notch. This portion was removed. The distal end had apparently sloughed away. Recovery was uneventful. Sections of the appendix showed the ova of the bilharzia. As to the mode of entrance, the authors conclude that the patient first had an appendicitis which left him with a sinus leading to an abscess cavity in close connection with the proximal part of his appendix, and that later this sinus was the portal of entrance of the bilharzia, while he was bathing in an infected stream. Full pathological details and two figures accompany the case report.

Puerperal Sepsis Due to Bacillus Coli Communis.—A. K. Gordon's patient, a primipara, originally confined by a midwife, did well till the fifth day, when she developed the usual evidences of sepsis. No physician was summoned, until the seventh day; but he, as soon as summoned, ordered her removal to hospital, which she reached in an apparently moribund condition. Under curetting, antistreptococcus serum, etc., no definite progress was made toward recovery. As various cultures showed nothing but *B. coli communis*, 100 c.c. of serum prepared from a horse which had been injected with five pure cultures of *B. coli*, were administered. The effect was most marked, and from this time the patient began to improve and made an uninterrupted recovery.

Enlarged Glands of the Neck Successfully Treated by the X-rays.—The patient of M. E. Dovaston was a girl of eighteen years, with enlargements on both sides. Treatment continued over a period of nine months. The exposures were given for the first two months four

times a week, afterwards three times, and the last five months twice a week. The improvement was at first evident in the disappearance of the tissues binding the glands together, after which the individual glands became more definite. The glands themselves then gradually lessened and eventually disappeared, leaving a perfectly formed neck on either side; no recurrence at time of report (eight months).

British Medical Journal, February 10, 1906.

Arteriosclerosis.—J. Mackenzie refers to a series of patients seeming to run in families in which evidences of arteriosclerosis have appeared relatively early in life. He thinks they may illustrate the beginnings of permanent high vascular pressure, arteriosclerosis, gouty kidneys, etc. One patient had dyspnea, palpitation on exertion, thickened arterial walls, a pulmonary apoplexy at thirty-seven, and a fatal cerebral hemorrhage at fifty-nine. A sister of this patient suffers from similar circulatory and respiratory attacks, but is always relieved by the iodide. A daughter of the first patient has a mild form of Raynaud's disease, and has told the author that both the mother and aunt had the same symptoms when at her (the daughter's) age. Still another case in another family is related, presenting similar symptoms. Concerning the causes of arteriosclerosis, the author notes that the mischief is generally done by the time the case comes under observation, and the cause is usually attributed to an agency that suits the physician's fancy. He records his advice to one patient under such circumstances, to avoid beer and spirits, and eat less butcher's meat. It turned out that the man was both a teetotaler and a vegetarian.

Idiosyncrasy to Mushroom Poisoning.—E. E. Frossard relates the case of a young woman of thirty who, while cooking mushrooms for the family breakfast, ate some raw. Three hours later she purged, was nauseated, and immediately became unconscious. Two hours after she was dead. In the stomach twenty mushrooms were found, and where they lay was a zone of acute inflammation. Otherwise the organ was normal. Other members of the household who ate the cooked mushrooms suffered no ill effects. At the time of the occurrence, the rain had fallen incessantly and the mushrooms were sodden with water. They should always be cooked on a gridiron over a clear fire till all the liquid they contain has been exuded.

Food Fever in Children.—Under this title, Eustace Smith describes a condition, the symptoms of which are as follows: The subjects of the complaint are usually neurotic children of either sex, between the ages of three or four and ten or twelve years, or even younger. The attack begins with headache, accompanied sometimes by vomiting, sometimes by looseness of the bowels, but always by signs of some kind of digestive upset. The child lies about with a dull, pasty face, a dirty tongue; he does not care to play, and has a temperature of from 101° to 105°. If the abdomen is examined, the stomach resonance is found to reach higher than normal—often nearly as high as the left nipple—and the edge of the liver can be felt one or two fingerbreadths below the costal margin. The water is very high-colored, or thick, and very acid. Smith believes that these cases are primarily attacks of acute gastric catarrh. Unloading of the liver by a good mercurial purge lowers the fever, but it generally rises again from autointoxication. Milk diet is contraindicated. The children should have such foods as mutton, poultry, white fish, green vegetables well boiled, eggs, butter with stale bread or toast. Salted foods are also allowable. Even a small amount of milk may keep up fermentation. These patients are peculiarly susceptible to chilling from exposure, and must be properly protected.

The Relation of Angina Pectoris and Allied Conditions to an Arteriocardiac Reflex Having Its Origin in the Abdomen.—This subject is discussed by W. Russell, who discusses the various significations which have been attributed at various times to the term "Angina Pectoris" and alludes to earlier observations on the blood supply and muscle pain as referred to the heart. He believes that many attacks have their origin from an arterial reflex existing in the abdomen. During digestion there is an influx of blood to the whole splanchnic area balanced by a systemic arterial contraction. This latter is evidently a reflex phenomenon originating in the splanchnic system and there transmitted to the systemic arteries. The latter become smaller in caliber, while their walls are thickened. The degree of change depends on the nature of the meal taken. In the wine drinker and heavy eater there is a rise of blood pressure and a true increase of arterial tension. The continued effect of this reflex is to produce arteriosclerosis, and we know that sclerosed vessels are peculiarly liable to hypertonic contraction Angina pectoris, then, is the result of an overaction of the normal abdominal reflex, manifesting itself through the sequence of changes just enumerated. Several illustrative clinical histories are given, showing the production of anginoid attacks from taking nourishment, from digestive disturbances, and from physical effort. In one case an attack was brought about by palpation of the epigastrium. Whatever the degree of intensity the heart-pang may reach, it is always the result of a sudden embarrassment of the myocardium, and usually and chiefly that of the left ventricle. This sudden heart embarrassment, varying widely in degree and intensity, is the one fact common to all the divisions or subdivisions under which all cases have been classed. The angor animi, which also varies in degree, is, the author thinks, common to all sudden heart embarrassments, which fall short of being so immediately fatal that there is no time for the development of such sensations. The cause of the sudden heart embarrassment in the vast majority of cases is the arterial hypertonic contraction, or spasm contraction we have been considering, the latter term indicating the more sudden and severe degrees of contraction. Even toxic conditions only give rise to angina when the factors indicated are present. By the cases reported the author has shown that this hypersensitiveness of the vasomotor center, even in grave angina pectoris, can be reduced, controlled, or even removed by dietetic measures, with the result that the anginous seizures are removed or greatly modified. In cases where the arterial spasm is associated with great anatomical change, either in the myocardium or in the coronary vessels, absolute cure can hardly be looked for; but in all cases the symptoms of angina pectoris may be much ameliorated by accepting, as a working hypothesis, the propositions above submitted and conducting the treatment in accordance with what they indicate.

Berliner klinische Wochenschrift, February 5, 1906.

The Fate of the Different Sugars in Diabetics.—Petitti experimented on diabetics by injecting different solutions containing 50 grams each of glusose, levulose, cane sugar, and lactose into the rectum and comparing the results of the analyses of the urine and stools under these conditions with those obtained when the same amount of the same sugar was given by mouth. He comes to the conclusions that sugar given by rectum is absorbed as such no matter of what variety it is. It is not likely that any marked bacterial fermentation takes place in the bowel. It is not possible to state with certainty that sugar absorbed through the rectum is more fully used than that taken by mouth, for in some instances the one condition obtains and in others the other. On what factors this variability depends is still unknown. No matter what sugar is given to a diabetic, either by mouth or by rectum, in quantities of 50 grams an increased excretion through the urine takes place, and this increase always consists of a dextrorotary sugar. It is impossible to say what variety of sugar is most fully used by the diabetic organism, but lactose appears to be most fully used and cane sugar the least. In severe cases of diabetes in which acidosis already exists this condition is not altered by the administration of sugar either through the mouth or the rectum, and the sugar excretion remains unchanged without being much influenced by the administration of the added amount. Enemas of sugar, and particularly those of lactose, should be found useful in the treatment of diabetes.

Endoscopy of the Urethra.—Goldschmidt describes an instrument by means of which inspection of the urethral canal is greatly facilitated. He makes use of the principle of the cystoscope and applies it to the present use by dilating the urethra with water. The instrument bears at its distal extremity a miniature electric lamp, and the wall of the tube has two large windows extending for a short distance proximal to the electric lamp. An ocular may be inserted in the proximal end of the instrument, and suitable provision for irrigation by a stream of water is also made. In practice the instrument is inserted to the desired depth and the canal distended to any desired degree by the pressure of the irrigating fluid. On setting the lamp in operation a satisfactory view of the urethral mucosa is said to be easily obtainable.

Chronic Progressive Chorea in Youth.—Lange says that while Huntington's chorea is ordinarily a disease of advanced life, usually occurring between the thirtieth and fortieth year, in certain instances the disease is observed in individuals much younger than this. Heilbronner has also called attention to the fact that familial chorea in general shows the tendency in each successive generation to attack individuals whose average age is less than that of those in the preceding one. In other words, the disease is progressive not only for the individual, but also in its familial tendency. The author's patient was a man of twenty-six, who developed the disease in typical

orm shortly after having been subjected to brutal treatment during his period of military service. His father developed the disease at the age of forty-eight years, apparently as the result of trauma in the farm of a fall from a high wagon. As no other ancestors who had had the disease could be discovered the author assumes that the father must be regarded as the originator of a familial tendency.

Münchener medizinische Wochenschrift, February 6, 1906.

Seroactivity and Phagocytosis.—Gruber and Futaki while emphasizing the importance of phagocytosis in the defense of the body against infection, believe that it must be placed second to the substances contained in the blood serum. This conclusion is based largely on experiments dealing with the opsonins. On placing virulent typhoid bacilli in contact with living guinea-pig leucocytes plus inactivated serum phagocytosis occurred much more slowly than when the experiment was repeated with unheated serum. The authors believe that the circulating serum contains a substance, the opsonin, which may or may not be identical with the alexin, and which has the property of extracting from bacteria, or causing them to give off, substances which incite the phagocytic activity of the leucocytes. The function of the thermolabile bodies of the blood serum lies not so much in their ability to destroy bacteria as in this property of stimulating phagocytosis. The action of the active serum by which bacteria are made the prey of the leucocytes is *per se* as little damaging to the vitality of the bacteria as is the process of agglutination.

Hirschsprung's Disease.—Bittorf describes a case of this disease, which is interesting in that the autopsy was secured at the age of only nineteen and one-half weeks. The patient came under treatment for bronchopneumonia, but in addition exhibited evidences of fecal retention and presented a tumor of large size, situated in the left hypochondrium. After an illness of several weeks, the infant died and was found to have pulmonary tuberculosis and Hirschsprung's disease. The seat of the dilatation of the intestine was the entire sigmoid flexure and the junction between sigmoid and rectum and sigmoid and descending colon was sharply marked by a pronounced stricture. The descending colon was not enlarged. The distended sigmoid extended upward to the costal arch on the left side and displaced the liver downward and to the right.

Observations on the Treatment of Acute Suppurative Processes with Bier's Hyperemia.—Colley warmly praises Bier's treatment, and predicts that in the future it will occupy a prominent place in surgical methods of procedure. He advises great caution on the part of practitioners, however, in attempting to introduce the method, because not only must the technique be acquired, but also popular opinion is so strongly in favor of promptly incising all suppurative processes that a plan of procedure which does not carry out this principle, and even temporarily increases the local swelling, is not likely to be regarded with favor by the laity, and experiences tending to bring the method into discredit may easily be encountered. By bringing bacteria of known virulence into contact with edema fluid taken from a congested limb, the seat of a suppurative process, the author was able to prove that a distinct bactericidal action not present in serum from a normal limb was developed in the body fluids of a region subjected to the congestion treatment. He also noted that in many instances, application of the treatment caused a general swelling of the lymph nodes in all parts of the body. Colley speaks very highly of the value of the method in such conditions as puerperal mastitis, buboes and furuncles, but states that sever diabetes is a contraindication to the treatment. He also disapproves of the application of general congestion to the head by means of the neck bandage, owing to the intracranial hyperemia that must be produced. He has found that warm baths of the entire body after the removal of the congesting bandage or suction cup have a beneficial action and appear to accelerate the cure. He also speaks of striking results obtained in eczema by the congestion treatment

Deutsche medizinische Wochenschrift, February 8, 1906.

An Experimental Observation Relating to Siegel's Syphilis Inoculations in Animals.—Wechselmann describes the rather striking cutaneous lesions which Siegel obtained on inoculating monkeys, principally maccacs, with blood and kidney emulsion from rabbits infected from human syphilis. The lesions produced in the monkeys were so extensive that it seemed as if the virus must have undergone some increase in strength by passage through the rabbit, as monkeys of the lower orders directly inoculated from human lesions do not exhibit very marked evidences of infection. Wechselmann was led to make a control experiment on a monkey by inoculating it in a manner similar to that described by Siegel, with blood from a healthy rabbit. Three c.c. of this were injected subcutaneously into the animal, and about three weeks later lesions began to appear in the palms of the paws, and later on in other situations which strongly resembled Siegel's descriptions of his results with material taken from syphilitic rabbits. Wechselmann therefore concludes that Siegel's experiments so far do not permit positive deductions in regard to the nature of the lesions produced by his inoculations.

Bier's Congestion in Acute Suppurations of the Ear.—Stenger says that the opinions of otologists in regard to the value of Bier's treatment by hyperemia in suppurative ear diseases are not entirely in accord, some writers expressing views rather adverse to the method, while others esteem it highly. He reports the results he himself obtained in eighteen cases of acute suppurative conditions, and states that he believes that the method will be found of distinct value in otology. He employed two methods of producing the congestion, first by means of a rubber neck bandage and secondly by the use of suction cups. In suppurative otitis media the author believes that the treatment with the rubber bandage may be begun as soon as diminution in the severity of the symptoms has begun under the influence of the ordinary treatment, as recovery may be hastened by the congestion treatment under these conditions. If alarming symptoms develop from the start, the congestion treatment should be employed at once in additions to the usual measures, without, however, deferring unduly operative intervention, should this seem necessary. In cases with involvement of the mastoid the author makes the skin incision and evacuates any pus that may be under the periosteum and chisels a narrow passage to the antrum; a suction cup is then applied to the wound and allowed to remain for several hours. Large amounts of secretion are usually obtained, and the procedure is repeated for shorter periods of time on the succeeding days. In cases without abscess but in which there is swelling over the mastoid with tenderness to pressure, a small skin incision is made and an opening effected in the bone, though this need not penetrate to the antrum. By the application of the suction cup the mastoid cells can be effectually drained of any secretion present.

French and Italian Journals.

The Fatty Nature of Opalescent Blood Serum.—A. Gilbert and J. Jomier have been studying the nature of opalescent blood serum. Their experiments have included eight specimens. After agitating it with a certain proportion of ether, the serum is centrifugalized. There is a rapid separation of two layers, the lower one being the clarified serum, the upper having the appearance of a gelatinous disk. This disk is made up of an aggregation of particles of serum expanded by the ether; when treated with distilled water, there is noted an opalescent liquid analogous to that of the serum, and which presents under the microscope a multitude of refractory particles comparable to globules of milk. The particles turn brown by the addition of osmic acid after a contact of a few minutes. These investigators, having succeeded in coloring with osmic acid the particles which are separated from the serum by centrifugalization, have concluded that the nature of the opalescent principle of blood serum is fatty.—*Gazette des Hopitaux, Civils et Militaires*, January 25, 1906.

Dosage of Chloroform in the Blood.—Nicloux is continuing his interesting experiments relating to the dosage of chloroform in the blood by a most original and precise method. The results of his researches show that dogs are anesthetized when their blood contains on the average of fifty milligrams of chloroform to one hundred cubic centimeters of blood. Each animal, however, has an anesthetic coefficient which may vary from forty-five to sixty milligrams. The dose of chloroform necessary to cause the death of an animal is little more than the anesthetic dose. It varies between fifty-five and seventy milligrams. After the inhalation of chloroform has ceased, the quantity of chloroform in the blood rapidly diminishes, becoming scarcely appreciable a few hours later.—*La Presse Médicale*, January 24, 1906.

A Case of Tuberculous Cervical Metritis.—L. G. Richelot calls attention to the rarity of reported observations of tuberculous cervical metritis. He himself has had such a case under his care. The patient was a woman clearly tuberculous. She coughed and there was evidence of small cavities. The cervix was the seat of an extensive ulceration, showing drops of pus on the surface. The consistence was that of metritis. The writer did not believe the affection to be an epithelioma, but he suspected tuberculosis of the cervix and thought that the rest of the genital apparatus must be involved. He therefore performed a hysterectomy. Histological examination demonstrated the nature of the trouble.—*Annales de Gynecologie et d'Obstetrique*, January, 1906

Book Reviews.

A Text-Book on Modern Materia Medica and Therapeutics. By A. A. Stevens, A.M., M.D., Lecturer on Physical Diagnosis, University of Pennsylvania; Professor of Pathology, Woman's Medical College of Philadelphia. Fourth Edition, Revised. Philadelphia and London: W. B. Saunders & Company, 1905.

The eighth decennial revision of the U. S. Pharmacopeia has necessitated a new edition of this standard and deservedly popular treatise. In this issue the work has been made to accord with the changes in name and strength of the pharmacopeial preparations, some of which are quite radical, and there have also been added new sections on ethyl chloride, radium, scopolamine, and other therapeutic agents which have sprung into prominence since the third edition. Among the numerous treatises on this most important branch of medical practice, this of Dr. Stevens has ranked with the best, and the new edition, now offered to the medical public, preserves its reputation as one of the authoritative works on materia medica and therapeutics. The author's spelling of the alkaloids is, however, shockingly bad.

Dose-Book and Manual of Prescription-Writing; with a List of the Official Drugs and Preparations, and the More Important Newer Remedies." By E. Q. Thornton, M.D., Assistant Professor of Materia Medica, Jefferson Medical College, Philadelphia. Third Edition, Revised and Enlarged. Philadelphia and London: W. B. Saunders & Company, 1905.

The publication of the new edition of the U. S. Pharmacopeia has necessitated a revision of all the standard works on materia medica and therapeutics, and of this excellent little manual as well. Dr. Thornton's is not a treatise on materia medica or therapeutics, but it is a useful companion to any such work, giving a great amount of information on dosage, solubility, official preparations, etc., in a most convenient form for reference. In the appendix is a table showing the changes in strength ordered by the new pharmacopeia. It is a book especially designed for the student and young practitioner, but as a work of reference will find a place on the shelf of the busy physician who may wish to refresh his memory regarding the strength of a certain preparation or its dose, and has not the time to consult a large work.

Organotherapy, or Treatment by Means of Preparation of Various Organs. By H. Batty Shaw, M.D., F.R.C.P. Illustrated. Chicago: W. T. Keener & Co., 1905.

Among modern therapeutic methods, the employment of animal organic extracts is of particular interest and value, but the literature on the subject is scattered through so many periodicals and monographs that it is practically inaccessible for general use. The necessity for a compact yet comprehensive manual seems to be filled by this little book, which contains brief accounts of the physiology of the various glands of the body, in addition to a review of the practical application in disease of the derivatives of the organs. At the present day a working knowledge of the principles of organotherapy is a necessity for every competent practitioner, and the essential facts are here gathered and presented in a concise and attractive form. The development of this mode of medication is also traced in a very interesting manner in an introductory chapter.

Blakiston's Quiz Compends. A Compend of Diseases of the Skin. By Jay F. Schamberg, A.B., M.D., Professor of Diseases of the Skin, Philadelphia Polyclinic and College for Graduates in Medicine; Fellow of the College of Physicians of Philadelphia; Member of the American Dermatological Association. Fourth Edition, Revised and Enlarged, with 108 Illustrations. Philadelphia: P. Blakiston's Son & Co., 1905.

This edition of Schamberg's Compend on Diseases of the Skin contains a new chapter on actinotherapy and radiotherapy; otherwise it appears to have undergone no change. The book is well illustrated and will doubtless continue to be a favorite with students.

Der Aerztliche Ratgeber in Bild und Wort. Atlas und Hausbuch für Gesunde und Kranke. Unter Mitwirkung von Dr. G. Brühl, D. F. Crämer, Dr. Karl Grassmann, Dr. O. Haab, Dr. A. Jordan, Dr. H. Kerschensteiner, Dr. Albrecht Krecke, Dr. Paul T. Müller, Dr. W. Praussnitz, Dr. Gust. Preiswerk, Dr. A Schlossmann, Dr. Ludwig Seitz, Dr. W. Weygandt, herausgegeben von. Dr. Med. Fr. Siebert. München: J. F. Lehmanns Verlag; New York: Paul B. Hoeber.

This book is one that would serve admirably as an introduction to the whole science of medicine, but it is less commendable as a family guide. It is not so much that directions for self-treatment are given, for much care has apparently been exercised in this regard, but too much stress is laid on the graver and fatal aspects of disease, with a Teutonic bluntness that appears out of keeping with a spirit of true kindness to the layman. The discussions of the various subjects, particularly of pathological questions, seem unnecessarily detailed in many respects, but the reviewer's objection to the work is based mainly on the illustrations. These have been supplied in the greatest profusion, and a large number of them are well adapted to serve their present purpose. Others, however, furnish a picture gallery of horrors, repellent enough to exert a very undesirable effect on the average lay reader. We can see no justification for inserting in such a book, which is intended mainly for the perusal of mothers of families, and is likely to fall into the hands of children, these disgustingly lifelike presentations of the most extreme cases of loathsome skin diseases, fatal cases of burning, gangrenous limbs, revolting bed-sores, advanced facial cancer, etc., while the benefit to the non-medical reader of representations of the fundus oculi in such conditions as diabetic rettinitis and choroiditis is also doubtful. The book is so admirable in many respects, and the advice in matters of hygiene, nursing, and prophylaxis is so sensible and practical, that it is a pity it suffers from these other blemishes, which render it unsuitable for the family bookcase. Physicians could read it with profit, for it touches on many practical matters that often do not suggest themselves to the practitioner, and to them we can recommend it, but we should certainly hesitate before placing it in the hands of a patient.

Contribution à l'Étude de la Funiculite lymphotoxique dans les pays chauds. Par le Docteur R. Menocal, Professeur de Clinique Chirurgicale à la Faculté de Médecine de la Havane. La Havane: M. Ruiz y Ca., 1905.

In this pamphlet the author draws attention to combined lymphangitis and phlebitis of the spermatic cord. He describes four clinical varieties, and discusses their pathological anatomy and treatment.

Minor and Operative Surgery, Including Bandaging. By Henry R. Wharton, M.D., Professor of Clinical Surgery in the Woman's Medical College of Pennsylvania; Surgeon to the Presbyterian Hospital, and the Children's Hospital; Consulting Surgeon to St. Christopher's Hospital, the Bryn Mawr Hospital, and Girard College; Fellow of the American Surgical Association. Sixth Edition, Enlarged and Thoroughly Revised, with 532 Illustrations. Philadelphia and New York: Lea Brothers & Co., 1905.

In the successive editions of this popular manual the scope has been gradually enlarged, till now it includes almost all the surgery that the general practitioner requires. Among the more important of the additions may be mentioned tracheotomy, intubation of the larynx, and the operations for appendicitis and for strangulated hernia. The chapter on Bandaging is a model of its kind; the sections on Dressings, Ligatures, Anesthetics, Asepsis and Antisepsis, the treatment of Hemorrhages, and Minor Surgery in general, are all admirable. We note a few omissions, such as treatment of ingrowing toenail, removal of foreign bodies from the nose, ear, etc. For the general practitioner this is, without doubt, a very practical and useful manual.

Traitement de la Lèpre par le Palétuvier ou Manglier Rouge. Par le Docteur Matias Duque, Directeur et Médecin de l'Hôpital de Syphilis et Maladies Vénériennes, San Antonio; Colonel de Santé militaire de l'Armée libératrice de Cuba; et Lauréat de l'Université de la Havane. Paris: Edmond Dubois et Cie., 1905.

The writer of this little book describes his experience in the treatment of leprosy with the extract of red mangrove. His opinion of the efficacy of red mangrove is fortified by short histories of several cases in which the administration of this agent was followed by beneficial results. In view of the fact that leprosy is said to be increasing, this book is both opportune and important.

Nervous and Mental Diseases. By Archibald Church, M.D., Professor of Nervous and Mental Diseases and Medical Jurisprudence in Northwestern University Medical School, Chicago; and Frederick Peterson, M.D., President of the State Commission in Lunacy, New York; Clinical Professor of Neurology and Psychiatry, Columbia University. With 341 Illustrations. Fifth Edition, Revised and Enlarged. Philadelphia and London: W. B. Saunders & Company, 1905.

The most conspicuous alterations in this edition of what has come to be recognized as a standard text-book appear to be in the section on mental diseases. Kraepelin's classification of insanity has been added, and two new chapters have been written for the subjects of manic-depressive insanity and dementia præcox. The chnages in the first portion of the volume, though less evident, are numerous, and serve to keep it in accord with the progress that has been made in this department. The work has already been favorably discussed in these columns on several occasions, and it is a pleasure to commend it to those interested.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON OBSTETRICS AND GYNECOLOGY.

Stated Meeting, Held December 29, 1905.

DR. CHARLES F. ADAMS IN THE CHAIR.

Complete Rupture of the Uterus During Parturition.—Dr. L. A. LADINSKI reported this case. The patient was 34 years old; her menstruation began at 15, was regular, and she had had seven children and one miscarriage. Ten days before admission to Beth Israel Hospital she gave birth to a dead child after a very protracted labor. Since then she had been ill with pain in abdomen and left shoulder. Temperature on admission was 104°, the pulse rapid and feeble. Micturition was painful and difficult. A mass could be felt in the suprapubic region. Vaginal discharge was very foul and profuse, simulating sloughing cancerous tissue. On operation a large tear was found extending through the posterior wall of the cervix and posterior *cul-de-sac*, readily admitting the passage of the hand into the peritoneal cavity. The uterus was found to be extremely anteverted, the cervix pointing backward. Anterior and above the uterus a large mass could be felt which appeared to be placental tissue and blood clots. This was found to be blood clots and omentum adherent to the intestines and uterus. At the point of adhesion the omentum was in a state of necrosis. About six inches of omentum was ligated off and removed. The tear in the *cul-de-sac* was packed with iodoform gauze and the peritoneal cavity was drained in different directions. The patient made a slow but complete recovery.

Incomplete Rupture of the Uterus.—Dr. Ladinski also reported this case. The patient was 29 years old, had had six children with normal labors. Three weeks before admission to the hospital she fell and hurt herself. Two and a half weeks before full term she was in labor; twenty-four hours elapsed before the physician was called. He found her bleeding severely. Examination revealed a placenta prævia lateralis and he did a podalic version, delivered the fetus, then the placenta piecemeal, but still the hemorrhage continued. He then found an extensive laceration of the cervix. The uterus and vagina were packed with gauze and the patient stimulated energetically. Eighteen hours after delivery Dr. Ladinski saw the patient and had her sent to the hospital. On admission her pulse was from 180 to 200, and at times imperceptible. Intravenous infusion was given. Examination revealed a large tear through the cervix and body of the uterus on the left side, extending up to the fundus but not including the peritoneum. The layers of the left broad ligament were separated and the parietal peritoneum was dissected on the left side of abdomen to almost the umbilicus. Large clamps were applied to the ruptured borders of the uterus, the subperitoneal cavity and uterus were packed with gauze, and a tight abdominal bandage applied. The patient died a few hours later.

Spontaneous Rupture of Uterus in Seventh Month of Pregnancy.—Dr. Ladinski presented this specimen. The patient was 28 years old, whose menstruation began at 16th year. She had been married ten years, and had had three children and one miscarriage seven years ago. Last child was born five years ago, the labor being normal except for an adherent placenta. Four weeks after delivery she was curetted and immediately after complained of severe pain in the pelvis, had vomiting, distension in abdomen, and moderate obstruction of bowels. Shortly after she was removed to the hospital, where Dr. Torrens did a vaginal section on the day following. Seven months ago she became pregnant. Five days before Dr. Ladinski saw her she had slight pains and some spottings from the uterus. Examination revealed a normal position of the fetus, but no dilatation of the os uteri. Rest in bed and opiates was ordered and the bleeding stopped, but the pains in back and abdomen continued. At the end of five days she was found to be in a state of collapse, with severe pains in abdomen, extremely pale and restless, nausea, and vomiting spells. The respirations were rapid and gasping, the pulse thready, and at times imperceptible. The patient was removed to the hospital. The abdominal cavity was found to be filled with blood, both free and clotted, in which the fetus, with the unruptured amniotic sac entirely freed from the uterus, floated. The fetus was dead. The uterus presented a ragged tear about four inches in its right upper quadrant of the anterior wall. As there were several areas on the surface of the uterus which looked like old cicatrices he decided to do a hysterectomy. She made an uninterrupted and rapid convalescence. This was, in all probability, a case of rupture of the pregnant uterus caused by the presence of old cicatrices, the result of perforation either by the unskillfully applied curette, or, what was more probable, of tearing away parts of the uterine wall while attempting to remove particles of adherent placenta with the finger.

Pregnancy in a Woman with Imperforate Hymen.—Dr. Ladinski presented this patient, a girl 16 years old, with an imperforate hymen and yet seven months pregnant. She menstruated first in her 13th year and had only menstruated twice since. Upon examination there appeared to be a small opening in the hymen just beneath the situation of the meatus urinarius.

Dr. A. STURMDORF, referring to the pathogenesis of these uterine injuries, said that during the past year there had been much literature on this subject, especially regarding those occurring after cesarean section, and it was a fact that something more must be present than scar tissue. Some considered that rupture occurred when the placenta grew over the site of an old scar, thus rendering the scar more boggy and more easily stretched. Recently he saw what he believed to be a plausible explanation of rupture occurring after cesarean section; it was the softening of the scar due to the displacement of the decidual cells; if the mucosa was included in the sutures, or part of the mucosa was infolded between the muscular layers, when pregnancy occurred the cells in the muscular layer might become the seat of decidual changes, causing an extreme softening of the scar and rupture. He thought that possibly this was the cause of the rupture in the case reported. During the pulling of the injured parts some of the mucosa was included in the scar tissue, and during the subsequent pregnancy when the accident occurred the same decidual growth was present. The microscopical study of a section of the tear he thought would prove of interest.

Dr. A. E. GALLANT did not think it was fair to compare the scars resulting from cesarean section with those of a myomectomy. In one the wounds were clean cut, with clean sutures and primary union. It was well known that scars formed by granulation tissue, or, without suturing, were more friable than those resulting from clean-cut and clean-sutured wounds. This, in all probability, accounted for the smaller number of cases of rupture following cesarean section. He said he had seen an imperforate hymen so small that the two tiny openings could be found only with the greatest difficulty; yet this woman was pregnant to the fourth or fifth month and had an external and intravaginal gonorrhea as well.

Dr. LADINSKI said that a microscopical examination of the tissue about the tear had been made but the report was not yet complete. But the pathologist had told him that the piece removed at the scar showed degeneration of the muscular tissue; in other words, there was not only a degeneration of the scar tissue, but of the muscular tissue as well. He said that a scar formed after the removal of a fibroid that was imbedded in the wall of the uterus, when there was a raw surface to cover over, was more likely to break down than one formed after a cesarean section. He said he would not do a myomectomy in a child-bearing woman unless the myoma was a subperitoneal one.

Intestinal Gangrene from Mesenteric Embolism During Pregnancy.—Dr. A. STURMDORF presented this specimen. It was interesting not so much as illustrating a case as to

show a condition about which little or nothing was known. One and a half years ago Dr. Roswell Park of Buffalo described four cases of intestinal gangrene from mesenteric thrombosus or embolism whose etiological factors were obscure. He excluded all cases in which an apparent cause existed, those cases occurring in apparently healthy individuals. While the literature on the subject gave but forty-one or forty-two cases, not one of them had been published as occurring in the female or during pregnancy. Whether pregnancy had anything to do with its occurrence or not he could not say. By a strange coincidence Dr. Sturmdorf saw two cases in a comparatively short space of time. The first case he could get no details of and the specimen was lost. The second case was very interesting. The patient was a little woman in apparently perfect health. There was nothing in her previous condition to account for her trouble. There had been no intestinal trouble of any kind. Between the fifth and sixth months of pregnancy she suffered severe pain, and her attending physician suspected the occurrence of a premature labor, but there were no evidences of an impending labor. The abdomen became enormously distended; there occurred fecal vomiting and symptoms of intestinal obstruction. Abdominal section revealed gangrene of almost all of the jejunum and ileum. The nature of the trouble only became apparent when he had dissected the large mass. No large vessels were tied because they were occluded by thrombi. The patient died. He offered one theory as to the cause of the condition, that it was the result of a toxemia which produced ulcerative conditions within the intestinal mucosa. He believed this to be the only rational theory. All that was so far known of this trouble was that two sets of symptoms were presented, viz., the diarrheal and those of acute intestinal obstruction. When there was distension it was impossible to make a certain diagnosis. All these cases died, whether operated upon or not.

Fibroma Molluscum Gravidarum; a New Clinical Entity.—Dr. Samuel M. Brickner said that in the literature, after a very exhaustive search, no reference, even remotely associated with the theme, had been found, and he believed this communication to be the first to deal with the subject. He named the condition fibroma molluscum gravidarum for the reasons that clinically and pathologically the lesion corresponded with fibroma molluscum as known and described by dermatologists, and that the form discussed appeared only during pregnancy. Others had noted the coincidence of the two conditions, but, like himself, had supposed that the phenomenon had been recorded. It differed in no way histologically from the disease when found in males or in the non-pregnant, although its clinical course differed widely. It first appeared about the fourth or sixth month of pregnancy as small, slightly pigmented or non-pigmented sessile or pedunculated excrescences, which increased slowly in number as pregnancy advanced until, at full term, there might be as many as forty or fifty. Within a few weeks or months after delivery the excrescences lose their pigment and gradually disappear. No symptoms apart from the eruption were observed. They were distributed mainly about the neck. The lesions varied in size from a pin head to a split pea, projected above the surrounding skin, were often sessile, frequently having a small pedicle. Although the fibromata were very frequently pigmented, the pedicles of those which were pedunculated were always of the color of the skin. Upon their disappearance they left no trace nor scar. Their appearance was, in all probability, due to some disturbance of metabolism during pregnancy, and the best argument to this view was the fact that the lesions spontaneously disappeared within a short time after delivery, and at a time when other regenerative processes that followed parturition occurred. The prognosis was good and the treatment evident. After presenting the histological description of the tumors, of which more than a dozen were examined, by Dr. F. S. Mandlebaum, he recapitulated as follows: Fibroma molluscum gravidarum was a lesion of the skin appearing in the latter half of pregnancy, bearing the histological characters of fibroma molluscum, but differing from it clinically in its total disappearance post-partum at a time when the other regenerative processes were being completed. Its distribution was limited to the neck, the breasts, and the submammary area. The lesions were frequently pigmented; but this was not always the case and was not an essential element of the condition. The pigment ran from a light yellowish brown to a dark brown. The disease formed a clinical entity hitherto undescribed, whose essential elements were the appearance of fibrous mollusca during pregnancy and their vanishing post-partum. Pathologically the growths belonged to the group of fibroma molluscum.

Dr. S. Pollitzer thought that it was rather humiliating that dermatologists should call attention to gynecological conditions. The former rarely saw it. The women were not at all troubled by it and, if discovered, it was done casually, when the patient consulted the physician for something else. The condition was not at all uncommon among adults, but he had noticed a greater tendency to multiplication of these little tabs of skin in pregnant women, and their disappearance after delivery. These little tabs were not described in text-books at all. Fibromata mollusca as described in the text-books were a great deal larger, even to the size of apples.

Remarks on the Dermatoses of Pregnancy.—Dr. S. Pollitzer said that though there was no single disease of the skin that occurred exclusively during pregnancy and at no other time, they were nevertheless justified in speaking of the dermatoses of pregnancy as of a distinct etiological group, because under the influence of pregnancy, which produced profound metabolic, nervous, and vascular changes in the entire organism of which the skin was a part, diseases were noted which, as a matter of clinical observation, were in most intimate relation to the pregnant state. They included under the term (1) those diseases which occurred in a preponderating number of cases during the pregnant state, impetigo herpetiformis; (2) those whose intimate connection with pregnancy was manifested from the fact that they disappeared with the evacuation of the uterine contents, herpes gestationis, chloasma; (3) those transitory reflex vascular and nervous dermatoses like urticaria, erythema, hyperidrosis, of which they could say that they were found with relative frequency in pregnant women not subject to them during the non-pregnant state, and that their pathological character afforded some justification for assuming their relation to pregnancy. Finally, there was the influence of pregnancy on existing dermatoses to be considered. Impetigo herpetiformis was a rare and generally fatal disease which had occurred in 75 per cent. of the cases in pregnant women. This large proportion made it possible that pregnancy had a determining influence, though there was no other evidence, and the disease had the appearance of an infectious process. Herpes gestationis was a form of Duhring's disease. Dermatitis herpetiformis occurred in the gravid and disappeared usually as soon as the uterus was emptied. There was considerable ground for regarding the disease as due to an autointoxication. Chloasma gravidarum also commonly disappeared soon after delivery, differing in that respect from the similar condition known as chloasma uterinum. The condition to which attention was drawn by Dr. Brickner, fibroma molluscum gravidarum, belonged to this group of diseases which disappeared post-partum. These two diseases, chloasma and fibroma molluscum suggested an analogy with the papillary and pigmentary distrophy which was the principal characteristic of the disease which the author described in 1890, acanthrosis nigricans. In this disease cancer of the abdominal or pelvic organs was noted in over 75 per cent. of the cases, making it probable that the skin affection was a reflex of interference with the functions of the great ganglia of the abdomen or of the adrenal bodies. The mechanical effect of the gravid uterus in the production of edema and the interference with the venous current might produce secondary effects on the skin, pruritis, eczema.

The third group, which included urticaria, erythema, and hyperidrosis, rested on purely clinical evidence for their association with pregnancy, and they might be explained as in part due to interference with the intestinal function and in part to faulty metabolism, maternal or fetal. As to the relations of pregnancy to eczema, acne, etc., he denied the possibility of the production of these diseases by pregnancy, though he admitted that a smouldering eczema or acne might be lighted up in the disturbance of the vascular balance incident to that state. As to psoriasis, some cases got well and some grew worse during pregnancy, just as they did during any other equally prolonged period.

Dr. Samuel W. Bandler said that urticaria had been proven to occur more frequently during the pregnant state. It had also been proven that women during menstruation, during the gravid state, and at the menopause were more prone to disorders of various sorts which were explained on the metabolic theory.

Dr. William S. Stone said that, as a matter of fact, many of these dermatoses, as well as other manifestations of pregnancy, occurred in the early period of pregnancy when such factors as pressure of the growing uterus upon the abdominal nerves came into force.

Dr. L. A. Ladinski recalled a case of a patient suffering from pemphigus gravidarum and in which he thought the induction of labor was indicated, but not one of the consulting men would give a positive statement as to diagnosis or prognosis. The induction of labor though was followed by a slow cure.

Injuries to the Child's Head During Labor.—Dr. B. Sachs said that for many years he had been anxious to enlist the interest of the obstetrician and of the general practitioner in the injuries which the head of the child was apt to sustain during parturition. Dr. Sachs made the deliberate statement that the world is full of imbeciles, or paralytics, of epileptics, not only in our almshouses and public institutions, but in some of the best families, who might have been normal individuals if they had been given a "square deal" at the time of birth. Years ago his attention was called to the fact that of all the cases of infantile paralysis, a very considerable number were either first-born children or such who had been born after prolonged, often dry, labor. Careful statistics of several hundred of such cases showed that less harm was done by instrumental delivery than by prolonged labor; in such cases the skull and the brain were apt to be seriously compressed, followed by hemorrhage from the minute vessels, and an effusion of blood covering a smaller or greater portion of one or both hemispheres. The hemorrhage might be over one or both motor areas, and this one fact accounted for the frequent occurrence of spastic hemiplegias or diplegias that developed in very young children.

If the hemorrhage occurred over other parts of the brain a condition of imbecility or of epilepsy might develop with little or no paralysis. It was only in the extreme cases in which the symptoms of the injury done was so manifest that the physician could observe the harm done. In the larger number of cases slighter hemorrhages had occurred and the symptoms of paralysis, of imbecility, and of epilepsy were developed only within weeks, sometimes months, after birth, but the causal relation between the conditions at birth and the subsequent illness was none the less certain. He said he was firmly convinced that protracted labor was the most powerful factor in these conditions. It was wise to curtail the period of labor as much as possible and not necessarily wait until the child's heart action became feeble. Many children might have escaped epilepsy, idiocy, and paralysis if the period of labor had been properly managed.

Fore the severe cases of meningeal hemorrhage at birth, Cushing had recently suggested opening the skull and washing out the blood clots, and Dr. Cushing had cured two of four children on whom this plan had been tried. The hemorrhage that had occurred was bound to be followed by secondary changes, and the normal development of parts of the brain and central nervous system associated with it would be interfered with. One must depend upon prophylactic measures and upon more skillful manipulation of labor, and Dr. Sachs said that he could not help but feel that the medical man in attendance at confinements had for many years followed a policy of indifference toward the welfare of the child and had allowed too many children to be born in the world after labor unnecessarily prolonged and in conditions that were a distinct disadvantage to them and to society for the entire period of their natural lives.

Dr. William S. Stone did not think the picture drawn as to the attitude of the general obstetrician was at all exaggerated. He did think, however, that those men who were devoting themselves especially to obstetrics for years did realize the importance of avoiding these protracted labors. The whole question then came down to the dilatation of the cervix. It was taught in the medical schools that one could do almost anything after the cervix was fully dilated, and until that time we must go very slowly; this, of course, resulted in complete and incomplete tears of the uterus very frequently. It was but natural that the proper consideration of the integrity of the lower uterine zone should have possibly carried them too far. But in the long dry labors, which unfortunately were very frequent, especially in private practice, he thought that the discussion during the past year or two would have a great deal of value in calling the attention to the importance of devising means of dilating the cervix in a safer and more rapid way than had been had formerly.

In the cases Dr. Sachs had referred to, the more frequent use of the rubber dilating bags would be one of the best means that could be used at the present time to overcome such troubles. They were easily inserted and could be used in the early stage of labor and they were very efficient, especially in dry labors.

Dr. A. E. Gallant referred to a recent number of the *Annals of Surgery*, in which a French writer recommended the use of forceps as a dilator of the uterus in such cases, shoving the cervix over the blade of the forceps. With the French lock when the blades were approximated they came together and touched; therefore, in attempting to pull the head of the child through a tight cervix the blades would come down over the neck of the child and crush it. When the Hodge forceps was closed the tips would be about one inch apart; but when drawing them through a tight opening the blades here, too, would touch, thus endangering the child. He said that blades should be made so as not to lock that way, and he would condemn the French blades.

Dr. Jacobsohn said that the pressure was exerted by the inelastic bony ring of the pelvis in cases of flat pelves, especially upon the parietal bones and over the situation of the motor area, and that cases of infantile spastic paraplegia were not uncommon in these cases of obstructed or prolonged labors. The uterus was supposed to have an expulsive power of 50 pounds; the intermittent pressure was exerted upon these two points of the child's skull as it entered the pelvic brim and the part of the brain immediately beneath these points usually suffered. He did not believe the size of the head or the bony parts could be accurately measured *in utero* in a living woman. The reason labors were so protracted was not so much an undilatable cervix as because of the undilatable bony parts, the head being jammed into this hard, bony ring.

Dr. B. Sachs said that certain rules should be made for the guidance of those in charge of confinements, and his remarks were addressed particularly to obstetricians. As a rule the hemiplegias and epileptic disturbances would be observed early after birth and were not recognized immediately after birth because they were not looked for. With epilepsy and idiocy it was different. Epileptic disturbances might be due to meningeal hemorrhage occurring during delivery; epilepsy as such occurred only after secondary changes or processes had been engendered in the brain. The same was also true of idiocy. The first-born children were at a tremendous disadvantage.

AMERICAN DERMATOLOGICAL ASSOCIATION.

Twenty-ninth Annual Meeting, Held at the Academy of Medicine, New York City, December 28, 29, and 30, 1905.

(Special Report to the MEDICAL RECORD.)

THE PRESIDENT, DR. WILLIAM T. CORLETT OF CLEVELAND, OHIO, IN THE CHAIR.

(*Concluded from page* 320.)

Bullous Affections and Their Classification.—Dr. EDWARD B. BRONSON of New York City, in presenting this paper, said the term bullous diseases should be taken in a very restricted sense, inasmuch as a bullous eruption was nearly always the concomitant of some other disease. Of bullous affections there were two fundamental divisions: (*a*) Obstructive forms, in which bullæ occurred as the result of obstruction in the sweat follicles or in the lymph channels, with mechanical distention at the point of escape in the epidermis; (*b*) acantholytic forms, in which a vital impairment of the cohesion between the prickle cells enabled a relatively slight effusion of serum to force its way between the cells and produce a lacuna. Acantholysis might be a consequence (1) of external injury; (2) of absorption into the epidermis of venomous or infectious matter; (3) of some other cutaneous affection, which might be either symptomatic or idiopathic, and of which the bullous lesions were only an incident; (4) or finally, of some internal diseaes, transmitting an injurious influence directly to the prickle cell layer of the skin, in which case the bullous eruption might be a pathognomonic sign either of a localized skin lesion or of some more general disease reflected to the skin through the nervous system, but even in such cases the immediate cause of the bullous effect was very often some more or less slight and commonly overlooked local external injury.

The Classification of Bullous Diseases.—Dr. J. T. BOWEN of Boston, Mass., said it was generally conceded in the dermatological world to-day that the word pemphigus could no longer be accepted in its old sense as representing almost all bullous eruptions not due to traumatism, or which represented a stage in the evolution of some well-known dermatosis. It was equally certain that while an advance had been made in eliminating many forms from this class, no unanimity had been reached, and the subject was very far from being scientifically settled. The group that had been so ably described by Duhring as dermatitis herpetiformis had come to be regarded by almost all as entitled to its own place, although there were differences of opinion as to just what should be included in that group. Dr. Bowen said he would propose dividing the bullous dermatoses into the following provisional groups: (1) Acute infectious bullous dermatitis. This was the form that had been described as acute infectious pemphigus. (2) Chronic hereditary bullous dermatitis. (3) The form of bullous dermatitis which was described first by Neumann under the title of pemphigus vegetans. (4) The form of bullous dermatitis described as pemphigus foliaceus. (5) Dermatitis herpetiformis. The boundaries of this form could not at present be strictly drawn. (6) There remained a class of cases characterized by more or less constant recurrence of pure bullæ, without signs of multiformity, and with a certain symmetry of the lesions, which were frequently found on the mucous membrane. The affection was accompanied by very few subjective symptoms, and pursued a chronic and usually fatal course. This was the form described as chronic pemphigus by Brocq and Besnier, and was the prototype of the German pemphigus.

Dr. JAMES C. JOHNSTON of New York City, in opening the discussion on this subject, thought it was a good idea to eliminate the class of cases in which the eruption was accidental or infectious, or more rarely cystic. This, he said, narrowed the class, practically, to four clinical entities, namely, epidermoclysis bullosa, pemphigus, dermatitis herpetiformis, and pompholyx. In speaking in favor of the autotoxic origin of these lesions, he took up the changes that were constantly going on in the alimentary canal, and there, he thought, we had to look for most of the toxins that played a rôle in lesions of the skin. They might possibly be traceable to a failure of the process of digestion in the gastrointestinal tract, or to a failure of elaboration in the absorption of the intestinal products, which was chiefly carried on in the liver; or, thirdly, to a failure of elimination by the kidneys and skin. It was difficult to learn which of these three factors was at fault.

The discussion of the subject of the classification of bullous diseases was continued by Drs. Samuel Sherwell, L. A. Duhrling, M. B. Hartzell, Ravogli, J. Nevins Hyde, Jay F. Schamberg, Charles W. Allen, H. W. Stelwagon, William A. Pusey, H. C. Baum, and Charles J. White, and was closed by Drs. Bronson and Bowen.

Erythema Perstans, with Report of Two Cases Involving Circinate Lesions.—Dr. GROVER W. WENDE of Buffalo, N. Y., read this paper, in which he offered the following conclusions: (1) That we were dealing with a variety of skin affections which might be included under the general name of erythema perstans, which had points both of similarity and dissimilarity. In some, there were simple, chronic inflammatory patches; in others, diffused patches, papules, or nodules. Frequently evolution began in the center, and left annular or gyrate figures. (2) There seemed to be no law governing their duration, since they might last weeks, months, or years, or even during the entire life of the patient. The etiology might still be considered as obscure. No age was exempt, cases having been reported in children and in those advanced in years. The condition seemed to be more frequent in men than in women. (3) A study of the cases reported showed that the condition might be caused by intestinal toxemia, a gouty or rheumatic diathesis, or atmospheric changes. (4) The limited number of microscopical examinations that had been made revealed slight differences. All of the cases showed a superficial inflammation, dilatation of blood-vessels, infiltration of cells, and an edematous condition of the tissues.

Dr. JOHN A. FORDYCE said he had seen two cases similar to the ones reported by Dr. Wende.

Dr. JAY F. SCHAMBERG mentioned a case of annular, persistent erythema of the face and hands in a young man, which ultimately disappeared under the use of chrysarobin.

Dr. JAMES M. WINFIELD of Brooklyn reported a case of persistent erythema in a young girl which disappeared with the establishment of the function of menstruation.

Considerations on Pemphigus Vegetans.—Dr. A. RAVOGLI of Cincinnati, Ohio, read this paper. He stated that pemphigus vegetans was a malignant and grave form of pemphigus, its peculiar character consisting in the proliferation of the papillary layer, caused by the irritating qualities of the morbid secretions. It was constantly accompanied by alterations of the urine, as a result of diseased kidneys. In connection with his paper Dr. Ravogli detailed the history of a fatal case of pemphigus vegetans that had recently come under his observation.

Dr. M. B. HARTZELL reported a fatal case of pemphigus vegetans in which the skin lesions were comparatively insignificant, being limited to a number of bullæ and vegetations in the axillæ, with a considerable amount of pigmentation. The patient died without any discoverable reason for the fatal outcome.

Two Cases of Multiple Tumors of the Skin in Negroes, Associated with Itching.—Dr. JAY F. SCHAMBERG and Dr. ROSE HIRSCHLER of Philadelphia, Pa., presented the clinical histories of two cases of long-standing nodular growths in the skin of negro women. The disease was possibly the same as that described by Dr. W. A. Hardaway under the name "Multiple Tumors of the Skin Accompanied by Intense Pruritus." The essential features in the two cases, which were almost identical, were as follows: (1) The development of tubercles and tumors in the skin, principally of the extremities, accompanied by more or less severe itching. (2) The horny, resistant character of the epidermis overlying the growths. (3) The persistence of the

tubercles and itching for many years. (4) The recurrence of the nodules after extirpation. The two nodules which were excised in the first case were replaced by tumors of the same character as those removed. The cause of the disorder was undetermined. The theory that the growths might be the result of traumatism from scratching was borne out neither by the statements of the patients nor by the appearance of the lesions. Pathologically, the sequence of events appeared to be as follows: Dilatation of the cutaneous blood-vessels; cell infiltration, chiefly in sharply circumscribed masses; proliferation of the fixed connective tissue elements; formation of new collagenous fibers. A feature of more than passing interest was the great abundance of mast cells present.

Two Cases of Paget's Disease Treated by the X-Rays, with a Report of the Microscopical Findings in One of Them After Prolonged Treatment.—Dr. M. B. Hartzell of Philadelphia, Pa., said that from the results obtained by the treatment in the two cases of Paget's disease reported in this paper, and more particularly from the microscopic study of one of them after treatment had been continued for a considerable time, he believed we might conclude that the careful, systematic, and prolonged use of the *x*-rays might completely and permanently cure the disease of the areola and nipple, but he also believed that this agent had very little effect upon the epithelial proliferation in the ducts of the nipple, and in the alveoli of the mammary glands. If Paget's disease was in the beginning limited to the areola and surface of the nipple, the ducts and mammary glands becoming involved only after some considerable time, then we might hope, by the early and persistent use of the *x*-rays, to bring about a complete and lasting cure; but if the ducts and glands were involved in the process from the beginning the knife of the surgeon should be the first, and not the last, resort. Which of these two views of the malady was the correct one had, in the writer's opinion, not yet been definitely settled.

Dr. Francis J. Shepherd of Montreal, Canada, said that in any case that was at all suspicious of Paget's disease he would not wait for the *x*-rays, but would amputate the breast immediately, together with the adjacent lymphatic tissue.

Dr. J. Nevins Hyde said he agreed with Dr. Shepherd that in every well-defined case the complete ablation of the breast should be immediately done, followed, if it was deemed advisable, by *x*-ray applications as a prophylactic against a possible recurrence.

Dr. Samuel Sherwell of Brooklyn, N. Y., objected to classifying these lesions as Paget's disease when they occurred elsewhere than on the nipple.

Dr. Frank H. Montgomery reported two cases of Paget's disease treated by means of the *x*-rays. In one there was a recurrence near the site of the original tumor. In the other the lesion rapidly disappeared, and the patient had remained cured up to the present time, a period of one year.

Dr. Ravogli regarded the action of the *x*-rays in Paget's disease as only temporary, and he did not believe they could be relied upon to give permanent relief. The best remedy was the knife.

A Case of Chronic Ulceration in the Pubic Region.—Dr. S. Pollitzer of New York City reported the case of a married man, thirty-five years old, a native of the United States and a railroad employee. His present illness began at Richmond, Va., on October 20, 1904, when his attention was attracted to a small papule on the glans penis. Ten days later the papule was transformed into an ulcer, and within a few days a number of small "mattery sores," as the patient described them, appeared on the glans. Shortly afterward he noticed a small papule on the pubic region over the symphysis, from which a sanious fluid was discharged. A small papule, like that on the pubis, also developed on the left side of his forehead. This broke down and ulcerated, but eventually healed. The sore on the pubis, however, proved rebellious to treatment, increasing in area and attaining the size of a silver dollar. In March, 1905, the patient went to Hot Springs, Ark., where he spent nearly three and a half months under the care of Dr. H. P. Collings, who regarded the ulcerations as chancroidal. The patient for a short time was given mercury and the iodides, but under this treatment the ulcers seemed to grow worse. Locally a variety of applications were made, and the condition would improve at times and then again grow worse. Repeated microscopical examinations gave negative results, and spreads and cultures yielded only the usual crop of saprophytic organisms, excepting a single colony of a bacillus which the speaker said he had not been able to identify. It was apparent from its characteristics that it did not belong to the pyocyaneous group, with which, however, it shared some important features. A histological examination of sections cut from the border of the ulcers gave the usual picture of granulomatous tissue in a chronic inflammatory process of the skin. As the case was evidently not improving under external applications it was excised. The patient was subsequently operated on at the Garfield Hospital, in Washington, D. C., for a tumor of the testis, which upon histological examination was apparently syphilitic. In concluding his paper, Dr. Pollitzer expressed the opinion that this chronic ulceration in the pubic region represented a hitherto undescribed form of disease. That the bacillus that had been isolated was the cause of the ulceration had not been proven, but there was a certain degree of probability in favor of that view.

Dr. A. Ravogli said he could recall quite a number of cases of ulcerative lesions involving or surrounding the genitals, in which it had been very difficult to establish whether they were tubercular or syphilitic, or the result of a mixture of both these diatheses.

Dr. L. Duncan Bulkley said that in many of these cases the original lesion was much modified by the ordinary pus organisms which were everywhere present.

Dr. J. Nevins Hyde referred to a number of similar cases of his own in which the ulcerative processes were not syphilitic, as they had resisted the most vigorous and thorough anti-syphilitic treatment. They had been described under the title of chancroidal or lupoid ulceration of the groins, and the most satisfactory treatment that he had had any experience with was continued immersion. The patients were placed in a carefully regulated hot bath, which they left only for necessary purposes until the ulceration had cicatrized.

Dr. Charles W. Allen said he agreed with Dr. Hyde in regard to the efficacy of the permanent bath in the treatment of the class of lesions, which had been described under the name of porosis, and were probably the result of a mixed infection.

A Case of Recurrent Bullous Eruption of the Face; Probably Pemphigus Hystericus.—Dr. Francis J. Shepherd of Montreal reported the case of an unmarried girl of 20 who for the past eight years had suffered from a recurrent eruption on the face. This appeared first as small, inflamed blisters on the forehead, chin, cheek, and nose; these soon increased to the size of a ten-cent piece, became filled with bloody serum, then discharged and formed scabs. There might be half a dozen or more of these blisters at one time. As a rule the bullae came out in successive crops, and lasted about a month. They gave rise to burning, but no itching. There was no regularity as to where the spots might come out, but they had never appeared on the hairy scalp. The blisters left a pigmented mark after healing. Dr. Shepherd said the cause of the eruption was obscure. It was possibly connected with menstruation. The girl's general health was excellent, and the speaker said that he could not divest himself of the feeling that the eruption might be self-induced. At any rate, he was inclined to regard it as a trophoneurosis.

The final session of the Association was devoted largely to the presentation of patients.

Dr. C. T. Dade of New York City gave a demonstration of the uses of liquid air in the treatment of skin diseases.

*No reciprocity recognized by these States.

†Applicants should in every case write to the secretary for all test details regarding the examination in any particular State.

Wisconsin.—The Legislature of this State has recently enacted a law which empowers and requires the Wisconsin State Board of Medical Examiners to refuse to grant licenses or certificates of registration to persons guilty of immoral, dishonorable, or unprofessional conduct, and empowering the courts to revoke and annul any license or certificate issued to any person guilty of immoral, dishonorable, or unprofessional conduct, or fraud or perjury in connection with obtaining such license or certificate, or issued through error.

Oregon.—The Attorney-General of the State of Oregon is of opinion that any unsuccessful applicant before the State Board of Medical Examiners has the right, either personally, or by his agent, to see and examine the markings of his papers.

Virginia.—The following changes were recently made by the State Board of Examiners in regard to sections and number of questions. These will now comply with the requirements of the Confederation of Reciprocating Examining and Licensing Boards:

SUBJECTS	NO. OF QUESTIONS.
1. Anatomy and Embryology	10
2. Chemistry 6, Toxicology 2. Medical Jurisprudence 3.	11
3. Histology 2, Physiology 6, Hygiene 3	11
4. Materia Medica 6, Therapeutics 6	12
5. Pathology 6, Bacteriology 3, Neurology 3	12
6. Laryngology, Rhinology, Ophthalmology, Otology	10
7. Practice, Diagnosis, and Etiology	12
8. Obstetrics 5, Gynecology 5, Pediatrics 2	12
9. Surgery	10

New Jersey.—This State will endorse the medical license issued by any State after examination, provided that the educational, examining, and licensing requirements of that State are substantially equal to or higher than those of New Jersey.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week ending February 24, 1906.

	Cases	Deaths
Measles	1636	34
Diphtheria and Croup	341	77
Scarlet Fever	214	8
Smallpox

INTRACRANIAL LESIONS AS SEQUELÆ OF CHRONIC PURULENT OTITIS MEDIA.*

By M. ALLEN STARR, M.D., LL.D.,

NEW YORK.

PROFESSOR OF DISEASES OF THE NERVOUS SYSTEM, MEDICAL DEPARTMENT, COLUMBIA UNIVERSITY.

Before such an audience as this it is possible to take for granted a familiar knowledge of the frequency with which cerebral complications develop secondary to otitis media, and also of the cardinal symptoms which indicate them.

There are, however, a number of interesting points connected with this subject which are quite worthy of the consideration of both otologists and neurologists. And their discussion by such a gathering of specialists is quite likely to elicit facts and observations of great value.

I would like to consider with you (1) the possible cerebral complications of otitis media, (2) the symptoms which aid us in their diagnosis, (3) the proper methods of surgical treatment, and (4) the results of surgical operations for these complications.

I. The ordinary cerebral complications are abscess of the brain, meningitis, and sinus thrombosis. We are now obliged to add to this category acute encephalitis. This is an acute inflammation of the brain limited in its extent usually to the motor zone, but occurring also in any region. Strümpell was the first to describe it, and he thought it was most common in childhood. Oppenheim, however, has proven that it occurs in adults, and during the past two years many cases have been recorded. Further observation has shown that one of its active causes is otitis media. Voss[1] and Mygind[2] have recently reported several cases in which this condition was found either at autopsy or at the time of operation for supposed brain abscess. It consists of a limited area of hemorrhagic softening in the brain, either on the surface or beneath the cortex. It may be limited to the domain of one arterial branch. It is an acute inflammation, with congestion and minute hemorrrhages, and results in a destruction of the brain tissue, and as a result a sclerotic patch of greater or less extent is produced. It is not, however, fatal. Among Strümpell's cases, many got well. In the cases of Voss and of Mygind, recovery occurred. In these cases it is uncertain whether the recovery was spontaneous, or was aided by the free incision in the brain and by drainage which was established. In none of these cases has the incision revealed any pus.

The symptoms of acute encephalitis are very similar to those described as occurring in abscess, viz., the sudden appearance of acute cerebral symptoms, evidence of acute infection, fever, slow pulse, stupor, and, in addition to these general symptoms, certain local symptoms, sensory or motor aphasia, monoplegia, facial or brachial paralysis, or cortical epilepsy. There is no optic neuritis, there is no irregularity of the pupils, there is no vertigo, and little headache. In five cases of Oppenheim, the general symptoms passed away, the local symptoms remained as evidence of destruction of brain tissue. In one case which was trephined under the supposition that abscess was present, a fatal result followed, and the autopsy showed the condition described as acute hemorrhagic encephalitis without any pus. In one case of Voss which was operated upon, a bluish-gray-appearing tissue was found with a sharp line of demarcation between it and the normal brain. This measured about 6 cm. in diameter, and was located in the temporal lobe. Free incision failed to show pus, and the result was recovery. Voss reports two similar cases.

It may be thought that these cases are really cases of abscess in an early stage, which would have gone on to suppuration had no operation been done. But this theory is opposed by the record of Strümpell's and Oppenheim's cases, where without operation recovery ensued. Is it not possible, therefore, that in the occasional cases which all otologists have seen, where a cerebral complication has been suspected but not operated upon, and where recovery has followed, the real condition has been an acute encephalitis?

II. The symptoms of cerebral abscess. When a chronic otitis media is complicated by the development of an abscess within the skull, certain new symptoms not previously observed appear. These are (1) generalized or local headache of a severe and constant type; (2) a marked change in the mental state, consisting of dullness and hebetude, seeming lack of thought or great slowness of thought, irritability of temper, desire to be left alone, and to keep the mind at rest, imperfect power of attention, defective memory of recent events, and a feeling of depression; (3) tenderness of the head to percussion, and in some cases, as the tension within the cranium increases, a change in the tone elicited by percussion on one side when heard through the stethoscope; (4) abnormal temperature, whose variations are not pathognomonic of any one of the various conditions possible; (5) a pulse which varies with the temperature in meningitis, but is liable to be slow in abscess and becomes slower as the case goes on; (6) facial paralysis, which if due to an affection of the facial nerve in its course along the posterior wall of the cavity of the ear, is on the side of the diseased ear, but which if due to brain lesion is on the opposite side; (7) optic neuritis, which is of great value, but does not develop until quite late, when it appears at all; (8) an initial contraction of one pupil, followed later by a permanent dilatation of that pupil, which is a frequent sign of abscess, but is, however, not a constant symptom.

These are symptoms which we all recognize as being of great importance in the diagnosis. And yet they are not invariably present. Some may be

*Presented at a meeting of the New York Academy of Medicine, February 1, 1906.

absent, and great variations in each of these symptoms have been observed in different cases, so that no one of these symptoms an be declared as pathognomonic of abscess. Any further help in the diagnosis will therefore be welcomed by the physician who suspects an abscess, but is still in doubt regarding the possibility of a meningitis.

There are two recently discussed methods of investigation which merit our attention. I refer to the examination of the crebrospinal fluid obtained by lumbar puncture, and to the examination of the blood.

The cerebrospinal fluid in a normal state is clear, contains few flocculi, and when 5 c.c. are centrifugated and carefully examined microscopically, only one or two leucocytes are to be found. In all syphilitic patients the number of leucocytes is very much increased, being as high as 80 in tabes, from 30 to 150 in paresis, and from 20 to 60 in cerebrospinal syphilis. In meningitis the number of leucocytes is enormously increased. Fuchs and Rosenthal[3] have found as high as 952 cells in tuberculous meningitis, and nearly 100 in general meningitis. And in the recent literature I find a large number of cases reported in which an increase in the number of leucocytes in the cerebrospinal fluid has been observed in all forms of meningitis. On the other hand, this is not true of abscess. In a number of cases collected during the past two years I have failed to find any record of an increase in leucocytes in the cerebrospinal fluid except in those cases where a complicating meningitis was present. In the history of case after case the record is made that the examination of the cerebrospinal fluid was negative. These cases have been collected from many sources and may be regarded as reliable. I think we may conclude that the examination affords a valuable differential point between abscess and meningitis.

It also affords another important indication. In meningitis it is almost uniformly stated that microorganisms have been found in the fluid. They are tubercular bacilli, or the diplococcus, or the pneumococcus, or some micrococcus. But in abscess such microorganisms, though searched for, have not been found. Thus Neumann[4] and Grunert[5] have recorded several such cases, and I can add one of my own. Here, then, we have another differential point.

The blood examination is of equal value. While any inflammatory state like that present in otitis media acuta is likely to increase moderately the leucocytes in the blood, a very great and sudden increase in their number is a very valuable indication of a new inflammatory complication. Thus, in a case of chronic otitis media we may find 8,000 or 10,000 leucocytes, but if a meningitis or a brain abscess develops, the number rises to 20,000 or even 35,000. Such a rise alone will indicate that we have more than a mere otitis media in our patient.

But this is not all. Our data as yet are not very extensive, but I think we may safely say that a more rapid rise in the number of leucocytes and a higher leucocyte count is found in meningitis than in brain abscess. Thus in two cases which I was able to contrast as they progressed simultaneously, and in which the autopsies showed the exact condition, it was observed that in the case of meningitis the leucocyte count on the second day of the disease was 9,000, on the third 11,000, and then rose on the fourth day to 22,000, and remained between 22,000 and 26,000 till death on the fourteenth day. In the case of brain abscess the number rose slowly from 9,500 on the third day of the disease up to 14,000 on the eighth day, but never went up above 15,000 up to death, which occurred one month after the onset.

There is another fact elicited by a blood examination which is important. A rapid rise in the ratio of the polymorphonuclear leucocytes to other elements in the blood has been observed in all cases of acute inflammatory process. Usually such a rise is to be watched for, and if the ratio changes from 65 or 70 per cent. up to 75 or 80, or 85 per cent., the probability of a cerebral complication is very great. I can cite a case in point.

This case warrants consideration here, though Dr. Dench, whose case it was, will probably report it in full.

In a woman whose mastoid had been operated upon for acute exacerbation of a chronic otitis, cerebral symptoms developed four weeks after the mastoid operation. These were the sudden onset of a motor aphasia with much paraphasia, the understanding of language being perfect, but her speech being a queer jargon, wholly unintelligible. In the absence of other symptoms, except headache, I supposed the condition to be due to a thrombosis of a branch of the Sylvian artery, as she had well-marked arterial sclerosis and no other signs of cerebral abscess. This diagnosis seemed to be confirmed by the fact that for a week longer no other signs appeared. During this week, however, a slowly increasing leucocytosis was observed, the blood count made by Dr. Dixon showing a rise from 9,000 to 15,500 leucocytes, and an increase from 70 per cent. to 85 per cent. in the polymorphonuclear bodies. This convinced Dr. Dench that an abscess was gathering in the brain, a suspicion which was confirmed on the tenth day after the onset of the aphasia, when unmistakable symptoms of abscess appeared. This was found in the third frontal convolution by Dr. Dench at the operation, and was evacuated.

The question arose, in connection with the case, whether a corresponding leucocytosis could be due to a process of softening in the brain caused by a thrombosis. I have looked into this matter and have found that softening of the brain secondary to thrombosis, or to embolism, does not often, if ever, cause a leucocytosis, and does not raise the ratio of polynuclear leucocytes. A cerebral hemorrhage causes an immediate high grade of leucocytosis, but not a gradual rise. In this case, therefore, the blood examination proved to be a reliable indication of the development of a brain abscess, as distinguished from a clot or an area of softening.

It is of course impossible to draw wide conclusions from a single case, but I have found a number of confirmatory facts recorded in recent literature, and I think we may be warranted in stating that the examination of the blood may afford important data, first in determining that a cerebral complication is present, and, secondly, as to its exact nature. I can add nothing to the facts already in our possession in regard to the diagnosis of thrombosis of the lateral sinus as a complication of otitis media. But those facts are so clear that this complication seems most easy to detect from the typical variability of the temperature curves, the congestion of the jugular vein, and the enormous leucocytosis usually present.

III. The question of operative interference in cases where a cerebral abscess is positively diagnosticated is one that admits of but one answer. It is imperative to open the skull as soon as the diagnosis is made.

If the case proves to be one of brain abscess, it may be possible to find and to evacuate it, and thus to save the patient.

If the case proves to be one of meningitis, the

fatal termination is not hastened by the procedure.

But while I regard such operations as definitely indicated, I cannot but feel, after a considerable experience, that they are operations requiring special skill, and that they are not to be undertaken lightly.

Just as the general practitioner or the consultant in internal diseases is able to make a diagnosis of appendicitis, but is careful to call in a surgeon to operate, so I believe that both the neurologist and the otologist, while capable of making a diagnosis of brain abscess, should call in a general surgeon, or, if possible, a surgeon skilled in cerebral surgery, to operate. We admit the skill of some men in abdominal surgery, or in gynecological surgery, and many a competent and able practitioner, whether general or special, has no hesitation in referring his cases to them. Brain surgery is a department in which special skill and wide experience is essential to success, and this fact should be recognized and admitted, perhaps, more fully than it has been. It may seem a small difference to go on from the mastoid operation to cerebral surgery. It is, in fact, a very different matter. It requires different methods. It involves the use of different tools, and it puts one face to face with many complications often not appreciated until they arise, and which are sometimes impossible, with the knowledge and experience lacking, to meet. It is a notorious fact that men working along one line are often ignorant of what is being done along other lines. It is my fortune to be familiar with many methods of surgical treatment of brain disease, as a spectator at many operations. Permit me, then, to indicate what seems to me the proper method of operation in a brain abscess.

A brain abscess is always of very uncertain extent. It is therefore necessary to have a large field of operation. The head should be prepared twenty-four hours before the operation is done. It should be shaved all over, cleaned carefully by many scrubbings with soap, with alcohol, and with ether, and again with a corrosive sublimate solution. And a cap of sublimate gauze should be left on all night before the operation, and then at the time of operation the scrubbings should be repeated. Brain surgeons no longer use the trephine or the chisel in opening the skull. In hospitals an electric engine is used, first to bore five or six small holes in the skull, and second, to join these holes by a rotary saw. In this way a large opening four by three inches in size, preferably of omega shape, is made, and a flap of scalp and skull laid down. Or if an electric saw is not available, small trephine openings can be made and joined by the small Gigli saw or by a gouge. Thus a large field is open and ample room secured before the dura is touched. All hemorrhage from the scalp and from any arteries of the diploe is to be stopped before the dura is opened. The arteries of the diploe may be plugged with wooden points or with Horsley's wax. The flap is to be protected during the operation by being wrapped in soft sublimate gauze wet repeatedly with hot water at a temperature of 110°.

The dura is to be opened with great care. A semilunar incision is the best, following the line of the opening in the skull. A fine hook inserted lifts the dura away from the brain, a fine scalpel cuts a hole not more than a millimeter in length, and a blunt-pointed scissors is inserted in this hole and used to divide the dura. The dura is to be lifted away from the brain as the division is made, to prevent injury to the pial vessels.

When the cortex is exposed, several conditions may be found. There may be an abscess in sight which can be evacuated by an incision and drained. Aid the draining by turning the patient over so that the opening in the abscess shall be down, and gravitation will aid in emptying it. I have often seen this neglected, and in consequence the abscess was not really drained till the dressings were applied, the patient was in bed and lay on the side.

There may be no abscess in sight. Many abscesses lie a centimeter or more beneath the surface. They may be felt, the brain being softer at one point. They may be indicated by the greater venous congestion at one point in the pia. If not, it is justifiable to make a deep incision in the brain. Always incise along the summit of a convolution in its long diameter and separate the incised surfaces by two broad, flat spatulæ, which thus enable one to get access to the deeper part. Never thrust a finger into the brain. If a deep abscess is found, it is to be emptied by gravitation, the opening being kept open at the operation either by the spatulæ, or by the ear speculum divided and separated. The subsequent drain should be decalcined bone or rubber tissue folded, as horsehair is inadequate. If the pus found is thick, a gauze drain may act as a plug instead of a drain.

If a diffuse encephalitis is found, and not an abscess, it may be left alone, or it may be well to cut the congested and degenerated area out, leaving a cavity. The excision should extend to the limit of the degenerated area, and the walls left are to be normal brain. This involves hemorrhage, which may be stopped by gauze tampons held for some minutes in the cavity, to allow firm clots to form in the vessels. It may be necessary to leave such a tampon in for twenty-four hours. Sterile tampons are far better than iodoform gauze, which should never be used about the brain. I have seen serious symptoms of iodoform poisoning from the use of iodoform about the brain. It is quickly absorbed by the cerebrospinal fluid and thus invades the body.

During the entire operation very hot water should be run constantly over the surface of the brain. Horsley operates now almost in a pool of hot water, the temperature of the brain being kept at 103° all the time.

If a meningitis is found, and no abscess, a drain may be inserted.

When the operation on the brain and the insertion of a drain has been accomplished, the dura may be united, excepting at the posterior inferior angle or corner of the opening, where the drain is to be brought out. Here, too, an opening is to be made in the skull—one of the original trephine holes being utilized for this purpose. It may be well to enlarge the opening in the skull by the rongeur, where the drain comes out, so that no pressure shall be made on the drain. The scalp may be sewed up except about the drain, and the patient should be made to lie on the side of the abscess to encourage drainage. A very large absorbent cotton dressing held by gauze should be applied over the entire head, as it is important to exclude air from the wound. The dressings should be changed daily and the drain gradually allowed to be pushed out, but never removed.

I mention these points because I have seen abscesses found and imperfectly evacuated through too small openings, and subsequent fatal meningitis develop because the abscess drained into the meninges, and not outward.

IV. The results of surgical treatment of the intracranial complications of otitis media have been more and more favorable as the operative technique has improved.

Some of the statistics obtainable are as follows:

Kocher, in 1895, collected 92 abscesses operated upon, with 51 recoveries.

Oppenheim, in 1897, collected 196 cases of otitic abscess, with 96 recoveries.

Röpke, in 1898, collected 142 cases of abscess after otitis, with 59 recoveries.

I have been over the literature from 1900 to 1906, and have been able to collect 54 temporal, 25 cerebellar, and 2 occipital abscesses, in all 81 abscesses of the brain, secondary to otitis, in which an operation had been performed. In 6 of these nothing was found at the operation, but the abscess was discovered at the autopsy. In 42 cases recovery followed the operation. In 39 cases death occurred.

The cerebellar cases were particularly unfavorable, for of the 25 cases, 16 died.

In studying these cases, several comments have suggested themselves.

In the first place, in almost every instance it is evident that the operation was unduly postponed. In many cases it was not done until five or even eight days after an abscess was suspected. In view of the certainty of a cerebral complication in all of them, it seems from these cases that operation should always be undertaken at the earliest possible moment. Secondly, in the majority of these cases it is evident that the operation was very badly done, incisions being too small or badly located, and drainage being imperfect. In the 39 cases which died, meningitis occurring after the operation was the usual cause of death. Such a meningitis might possibly have been avoided had the drainage been free, the opening in the head large, and asepsis perfect. Thirdly, in the cerebellar cases few characteristic cerebellar symptoms were present, and in 14 of the 25 the cerebellum was investigated after the temporal lobe had been found normal. This coincides with our experience in cerebellar tumors, which often fail to give any characteristic symptoms, and in which the mortality at operation is extremely high. There is, however, a symptom of cerebellar disease which I have not found recorded in cases of cerebellar abscess, but which has been named by Dana[6], who has especially called attention to it—the cerebellar seizure. It consists of sudden unexpected attacks of extreme vertigo, roaring in the head, relaxation of the limbs, and falling to the ground in a semiconscious state; these attacks are sometimes attended by temporary blindness and tonic spasms. They occur especially with tumors lying in the angle between cerebellum, pons, and medulla—a place which is also a frequent site of abscess. It is possible that if attention of otologists is called to this symptom, it will be noticed in other cases. If a diagnosis of cerebellar abscess is made, time should not be wasted in exploring the temporal lobe of the brain.

A Society for the Suppression of Dust.—A society has recently been organized in Vienna which might with great benefit to the comfort and health of New Yorkers be imitated here. The purpose of the new Austrian body is the abatement of the dust nuisance in streets and public highways. Various proposed schemes for laying dust will be studied, and when thought sufficiently practical will be given actual trials in the streets.

MASTOIDITIS IN INFANTS.*

By SEYMOUR OPPENHEIMER, M.D.,

NEW YORK.

OTOLOGIST TO GOUVERNEUR HOSPITAL; LARYNGOLOGIST AND OTOLOGIST TO MT. SINAI HOSPITAL DISPENSARY; FELLOW OF THE AMERICAN LARYNGOLOGICAL, RHINOLOGICAL, AND OTOLOGICAL SOCIETY, ETC., ETC.,

While otological literature of the past decade has been made up in great part of the complications of chronic and acute suppurative otitis media and especially of mastoiditis in the adult, yet until a recent period the involvement of this portion of the temporal bone in the infant has received but little attention. Three factors apparently seem to be concerned in leading to the neglect of careful studies in this important class of aural affections, namely, a lack of appreciation of the radical differences in the osseous anatomy of the temporal bone of the infant and the adult; the lack of marked symptoms presented by middle-ear suppuration and mastoiditis in many cases; and finally, the non-recognition of the frequency with which aural suppuration occurs in infants.

While sufficient statistical data has not yet been accumulated to show, with any degree of accuracy, the frequency with which mastoiditis occurs in this class of patients, yet the now admittedly large proportion of cases of suppurative otitis that occur during the course of pulmonary, gastrointestinal and other diseases, points very clearly to a not inconsiderable percentage of cases of mastoiditis in very young children. The studies of Barth in this respect are illustrative, as he has shown that in six hundred hospital children in whom the ears were examined, forty per cent. had aural lesions. Hartman, in the examination post-mortem of the temporal bones of 108 atrophic infants dying of gastrointestinal disease, found 85 in which the mastoid antrum was filled with muco pus and bacteria. Preysing finds similarly 81 per cent., and, of 154 cases in but nine had perforation of the drum membrane taken place. A most important factor in this connection is that in infants, many cases of pus in the middle ear run along for a considerable period without any symptoms that are recognizable except by careful examination of the membrana tympani, yet in such instances the antrum may be full of purulent material, but localizing symptoms may be in abeyance.

Should there be a purulent discharge from the external canal, the presence of aural trouble at once becomes self-evident, but the diagnosis should be made before this time, for as will be seen later, serious bone destruction may be going on and yet the symptoms be so slight, that the attention of the physician is not directed to this portion of the body unless a careful examination of the ears be made in all sick infants, whatever be the nature of the affection present. It is most important, therefore, that under proper illumination the condition of the membrana tympani should be ascertained, and, in the majority of instances where aural suppuration is present, the changes in the drum will indicate the condition of the typanum and in part its adnexa, with the possible exception of a few rare instances where the tympanic membrane retains its normal appearance even with a collection of pus behind it. Where this unusual condition is present other evidence can usually be elicited that will guide one in making a correct diagnosis. It can therefore be readily seen that an examination of the membrana tympani is essential in practically all sick infants, and while the age of the child and its general restless-

*Read before the Metropolitan Medical Society, January 23, 1906.

ness often makes such an examination most difficult, yet with care and patience it presents no greater obstacles than that of the adult and in many instances is even not as difficult, as, owing to the position of the drum head, pathological changes are easily recognized, especially if the canal be straightened by gently pulling the auricle backwards and downwards and employing the largest speculum that will fit it without causing pain.

In order that the diagnosis and treatment of mastoiditis or, rather, antritis in infants may be properly appreciated, it is essential that a clear understanding be had of the differences in the temporal bone of the child and the adult, as the peculiarities of this affection in the infant depend entirely upon these factors. Inasmuch as at birth the osseous external canal has not developed, its place is supplied by the fibrocartilaginous canal. The soft canal is thus attached to the external surface of the annulus tympanicus, at this age forming the tympanic portion of the temporal bone, which later, as the child advances in age, becomes lengthened, while the cartilaginous meatus becomes proportionally smaller. At the inner extremity of the canal, the annulus is still incomplete abovein the portion forming, the Rivinian segment, while the superior and inferior walls of the soft meatus are to a greater or less extent in contact, so that they must be separated in order to obtain a clear view of the membrana tympani. These meatal walls are much thicker in the child than in the adult and thus become a factor of considerable importance when pus accumulates behind them, as under these circumstances the pathway of least resistance for the escape of the purulent material is not the external auditory canal as would ordinarily be expected.

As regards the tympanum proper, the vault is nearly as large as that of the adult: the tegmen is often incomplete, so that vascular channels are brought into direct communication between it and the cranial contents, this being further enhanced by the sutures still being incompletely united and thus explaining in great part, the prominence of cerebral irritation so common in children of an early age. The mucosa of the middle ear still shows its embryonal state and contains a large number of vessels, which allow of rapid tumefaction and predisposes it to inflammatory changes. The Eustachian opening into the anterior wall of the tympanum is much shorter than in the adult; it is also wider and the tympanic orifice is comparatively larger, while it is situated at a lower level so that drainage is facilitated from the tympanum in this direction. Also an important relationship to the tympanum is the petrosquamous suture which is found on its superior wall, and this dehiscence allows a free communication between the dura and the tympanic cavity. This suture in its continuation forming the squama mastoid fissure, also plays an important part in the exit of pus from the tympanum, as through it the purulent material may pass outward and appear beneath the skin behind the auricle. These sutures remain more or less patulous until the end of the first or second year The aditus ad antrum in the infant varies in form and position with the location of the antrum, and unlike that of the adult, is in the middle of the posterior tympanic wall, so that from the side of the antrum it forms a canal inwards and forwards, while a straight probe passed through it in this direction goes through the tympanum and enters the mouth of the Eustachian tube.

Concerning the mastoid process or that portion of the temporal bone which corresponds to the mastoid of the adult, in the fetus at term, does not exist, while in the child from three to five years it becomes perfectly sketched out, but it is only when the age of thirteen years is reached that it is modeled in miniature to that of the adult. In the newborn child, therefore, the mastoid as such can scarcely be considered, and it is but partially and irregularly developed during the first year by the absorption of cancellous osseous tissue, with the later development of its cellular system, although as the pneumatic spaces develop, from the antrum, it is usual at an early age to find a few cells in close relation with the former space. Irrespective of the age of the child or of the stage of development of the osseous tissue behind the ear, the antrum is always present and is located above and in front of the squamomastoid fissure and below the supramastoid ridge, although both these landmarks may be indistinct. In the newborn, this space is not only relatively but absolutely larger than in the adult, and it lies behind and at a higher level than the tympanic cavity. In its relation to the surgical anatomy of this region, it is surrounded by extremely thin osseous walls, and is rarely more than two to five millimeters from the external surface, so that operation for mastoiditis becomes relatively simpler in the child of this age than in the adult. As the usual landmarks for locating the antrum are generally not sufficiently developed to be of value, one must depend upon the characteristic appearance of the thin non-resistant cortex over this cavity. This is the so-called "spongy spot," consisting of vascular foramina perforating the bone from the exterior into the antrum and lying together in a more or less depressed area below the supramastoid ridge and above the external meatus. As a result of the numerous sieve-like perforations at this point, the bone is non-resisting to the curette, so that the antrum is usually entered with but little or no difficulty.

Other anatomically important points are the venous channels in relation to the area involved in the pathological changes, and of these the lateral sinus possibly is less exposed to injury during operative procedures than in the adult, as its position is generally a considerable distance from the antrum, irrespective of how forward its course may be. From the observations made by Cheatle, the petrosquamous sinus is usually well marked in infants, but disappears at a later age. This venous channel opens into the lateral sinus behind, and the middle meningeal vein in front, and it may be the pathway in infancy of an otherwise unexplainable intracranial affection such as a basic meningitis following the mastoid infection. The large size of the sinus in early life accounts for the greater danger of intracranial complications in children than in adults. As the inner table of the cranium in this region is excessively thin and often incomplete along the sutural lines, the danger of intracranial infection does not become eliminated even when the purulent collection bursts through the mastoid cortex, for although the internal pressure is thus apparently relieved, the infection may still spread through the sutures, or even through the thin substance of the squamous portion of the bone.

The marked variances in the course of mastoiditis at this early age present a most puzzling phenomenon, as in some cases extensive osseous destruction may take place without the general health being greatly affected, while in others especially following the acute infections, the symptoms may be so prominent that they are at once recognized, yet the destructive advance of the disease is so rapid,

that but little can be done toward checking it. This aspect being most clearly appreciated by Pomeroy when he states that the policy of waiting for external ear symptoms to arise in infants is entirely unwarrantable, because, as shown by Ponfick's study of one hundred fatal cases, spontaneous rupture had occurred in less than nine per cent., thus showing the great importance of an early recognition of middle ear suppuration and the necessity for prompt treatment before gross mastoid changes occur, as it can be taken for granted that when pus remains in the tympanic cavity for even a short period, the antrum is also involved to a similar degree.

The absence of prominent symptoms when the antrum is filled with pus, is well shown in a case seen recently in a child of nine months in the practice of Dr. Berthold Flesch. For two weeks there had been a mild grade of gastroenteritis which had cleared up, but at the same time the temperature remained from 101 to 102, the child was fretful, was rapidly losing weight, and had almost complete anorexia. As no apparent cause could be found for the illness, it was suspected that the ears might be at fault, and I was then called to see the case. Examination showed decided redness of the manubrial vessels, and the child flinched when firm pressure was made over the antrum on the left side, the opposite ear showing nothing abnormal. A paracentesis of the drum was made and a few drops of pus containing streptococci were evacuated, with a slight improvement in the child's condition for two days. The aural discharge continued, but the general symptoms remained as before. The usual mastoid operation was then performed and the antrum readily opened with a curette. This space was found to be filled with pus, drainage of which was rapidly followed by cessation of the discharge from the tympanic cavity and complete restoration to health within a few weeks.

Undoubtedly many deaths in infants ascribed to other causes result from a purulent inflammation of the mastoid antrum which has been unrecognized. In these cases the child usually has some digestive disturbance, a condition of marasmus follows, and a fatal termination ensues, as the constitutional influence of a purulent otitis is by far greater in the child than in the adult. Such a fatal termination is much more common than is generally supposed, and as in the class of cases to which attention is here directed, that is those in which purulent discharge has not as yet taken place or is very scant, the aural affection is apt to be entirely overlooked unless one bears in mind that one of the most frequent causes of otherwise inexplainable high temperature in infants, is the presence of pus in the tympanum and antrum. Death also occurs from this cause by secondary infection of the meninges, although a fatal issue from extension of the purulent inflammation to the intracranial contents is not as frequent as that by septicemia. Scheib reports an instructive case in this connection, that of an infant eight days old, which died from obscure general symptoms; the autopsy showed the presence of a bilateral suppurative otitis and leptomeningitis.

In general, the pathological changes differ but little from those of the adult, but the tendency toward greater destruction of bone is enhanced and caries is more frequently found. As a result of this destructive tendency in many cases, the deeper structures are damaged before the conditions are recognized. The seventh nerve may be involved with resultant facial paresis or paralysis, or pus may break through the cortex with the formation of subperiostial abscess, and even at this age sequestra of large size may be found with extensive disorganization of the bony walls. On the other hand, instead of the pus escaping externally, it may find the passage of least resistance to be in an internal direction, as in a case observed by the writer in which purulent leptomeningitis followed acute mastoiditis after measles. The autopsy showed pus filling the internal ear, probably finding its way to the meninges *via* the facial canal.

A class of cases is not infrequently encountered in which there is a free flow of pus from the external canal either following a spontaneous rupture of the membrana tympani, or after a paracentesis, but coincident with this, symptoms of mastoiditis develop and operation shows the already beginning or advanced destruction of osseous tissue, the following case being of this nature:

E. W., age eleven months, was first seen three days after the onset of acute otitis following measles. A purulent discharge had appeared from the meatus the previous day and coincident with this the pain had ceased. The membrana tympani showed a small perforation in the posterior inferior quadrant, and as this opening was not sufficient for drainage, it was enlarged with the escape of a large quantity of purulent material. No symptoms of mastoid involvement were present at this time and the general condition of the child was excellent, its temperature being normal. The patient was not seen again for five days, when it was found that the purulent discharge was extremely copious and out of all proportion to that which could be formed in the tympanic cavity alone. The temperature was but slightly above the normal and the general state apparently unaltered. Externally there was no evidence of any mastoidal involvement, palpation over this region being entirely negative. On account of the great augmentation of the discharge, it was apparent that further drainage was indicated, and with this end in view, a postauricular incision was made, exposing the bone in this region. The "spongy spot" was readily located and the osseous cortex was found to be dark blue in color, indicating beginning caries. With a sharp spoon this area was curetted, it being so friable that it crumbled away and immediately below it the antrum was exposed filled with pus. All the carious bone was then removed, the usual dressings applied, and rapid healing followed with complete cessation of the discharge.

Independent of these rapid, acute forms of mastoiditis without grave physical depression another general group may be differentiated, in which the course of the purulent inflammation is subacute, is not usually connected with the exanthemata, and there is to be noted a gradual sagging of the posterior wall of the external auditory canal akin to that of the adult type.

An example of this being seen in the case of L. B., aged fourteen months. Her parents had noticed a scant watery discharge from the right ear for about one month, but paid no attention to it.

During this time she would have attacks of diarrhea, lasting for two or three days and then disappearing, to again return as before. There had been a gradual loss in weight, constant irritability and more or less temperature. The condition of the ear had not attracted special attention other than the knowledge of the slight discharge being present, but finally on this account and the inability of general remedies to effect improvement, the child was first seen that an examination of the ear might be made. The canal contained but a scant amount of greenish mucopus; there was a perfora-

tion in the posterior superior quadrant of the membrana tympani, but only its anterior edge was visible, as the postérior wall of the canal was bulging, and to a great extent obscured the view behind it. There was no swelling behind the ear, but moderate pressure over this region was painful. With these indications present, operation was advised and as in the other cases the antrum was readily opened, found full of pus and granulations, and the bone external and anterior to it considerably necrosed. The necrosed areas were removed, the parts packed and an uneventful recovery rapidly ensued, with an increase in the child's weight to normal, and complete restoration of its health.

The general symptoms of mastoiditis vary in almost every case and are of value only in occasionally directing suspicion to the affected ear. Restlessness is often marked; crying is frequent; the lower jar may present a peculiar tremor when the pain is severe; rubbing of the occiput against the pillow is not infrequent, while the restlessnes is apt to be enhanced at night, especially if the ear has been discharging, then ceases with the extension of the inflammation to the deeper osseous structures. The temperature may be 104 or 105 degrees, and is of a vascillating character, especially when a discharge has been present and suddenly diminishes, but in the absence of such a local symptom, a rise in the temperature alone is of little value, but when examination shows during the course of an acute otitis evidences of retention, the presence of temperature is a valuable sign of mastoid infection. Unexplainable temperatures in infants should always direct attention to the possibility of aural disease. As being indicative of aural trouble, the child often hangs the head toward the affected side, vomiting, convulsions, and even coma may ensue. Deafness is a symptom generally impossible to determine at this early age. The pain is usually paroxysmal in character, growing worse at night, while during the day it is often for periods of time in abeyance. Some glandular swelling beneath the mastoid is ofttimes present, and pain is elicited on pressure over the tragus.

Often the sole evidences of the ear affection must be gained from a careful study of the child for several days, and thus ascertaining the character of the pain, the presence of septic symptoms which develop quite early after the mastoid becomes involved and the changes which occur in the tympanic cavity. Torticollis in infants is very suggestive, as is also loss of weight without apparent cause. The development of mastoiditis is often associated with bronchopneumonia, while, as shown by Hartmann, digestive disturbances associated with pus in the tympanic cavity and mastoid are not at all uncommon. Often the condition is not recognized until edema becomes well defined over the mastoid, as spontaneous perforation may occur with the development of a fistula in cases where the mastoid cortex is very thin, even within a day after the onset of the acute attack. The presence of a fluctuating mass, however, does not necessarily imply a cortical perforation, as the pus may burrow through the Rivinian segment and find its exit by way of the superior wall, dissecting the soft parts away from the bone.

The presence of a purulent collection behind the auricle, is much more frequent in infants than in adults on account of the aural conditions not being as promptly recognized in the former. The presence of pus beneath the periosteum adds greatly to the danger of infection of the cranial contents either by way of the mastoid-squamous fissure, or by localized caries of the squamosa occurring with interference with the vascular channels and direcr infection. In cases where the pus collection undet the skin is extensive, pressure over this region or over the tissues of the neck beneath the auricle will often cause a flow of pus from the external auditory canal.

Pseudomeningeal symptoms or meningismus is frequently seen associated with mastoiditis in infants, and it adds a conflicting factor to the recognition of the aural trouble, as it is so frequently present in the acute infections of early life and especially in gastrointestinal disturbances. In some cases the meningeal symptoms may dominate the clinical field and thus no suspicion of mastoid inflammation will be entertained until irreparable injury has been done to the hearing, or even the life of the patient sacrificed. In practically all these cases the meningeal symptoms promptly disappear as soon as the pus has been evacuated from the mastoid antrum and middle ear.

Notwithstanding the great destruction of the soft and osseous tissues which takes place and the frequent presence of signs of meningeal irritation, true intracranial complications are uncommon, even in spite of the close relationship which exists between the tympanum and antrum with the interior of the cranium by means of the numerous vascular channels. The meningeal irritation, however, undoubtedly results in great part from this close anastomotic relationship, but it must also be remembered that in many cases of intestinal involvement, the cerebral irritation present is the result of a coincident aural suppuration and not dependent upon the gastroenteritis. In a few instances, the mastoiditis may be masked by the symptoms of some other affection to which the ear disorder is but secondary, or the aural suppuration may exist coincident with another affection, yet there may be a definite causal relation between the two conditions, as in a case of scarlet fever, seen in the practice of Dr. A. J. Wittson, where there was a complicating purulent process involving the kidney and mastoid, the two manifestations being but the local expressions of the same general process.

In conclusion I would but call attention to the absolute necessity of a careful examination under proper illumination of the membrana tympani of all ill infants independent of whatever be the nature of the affection present.

45 East Sixtieth Street.

LITERARY GEMS FROM THE MEDICAL ESSAYS OF OLIVER WENDELL HOLMES.

By LOUIS E. BLAIR, A.M., M.D.,

ALBANY, N. Y.

A RECENT editorial in the MEDICAL RECORD discussed the address of Dr. Cullingworth before a branch of the British Medical Association (*British Medical Journal,* November 4, 1905). His paper "reviewed the almost forgotten essay of Holmes on the 'Contagiousness of Puerperal Fever,' in which he revealed, with the clairvoyance of the poet, the true nature of this murderous disease." This paper was read more than sixty-two years ago and was epoch making in medicine. Dr. Holmes has written other medical essays of great force and literary beauty, and it is thought that a brief review of them with a few selections may prove entertaining and instructive to the readers of the MEDICAL RECORD, as

* Read before the Albany County Medical Society, December 15, 1905.

they often have been to the writer. Holmes is and always will be interesting, and in fact no apology need ever be made for introducing anything he has written. His writings will always remain a perpetual source of pure delight.

Holmes was not a great believer in medical therapeutics and polypharmacy. New drugs and new names introduced into the materia medica were always repugnant to his conservative nature, and were as an ice bath to his sensibilities. In fact the names and synthetic preparations of the commercial medical laboratories of to-day would have driven him to sheer distraction. He was a great believer in the laws of hygiene and their application. His last thoughts were for medicine. He says in his essay entitled "Currents and Counter Currents" (1860): "Presumptions are of vast importance in medicine as in law. A man is presumed innocent until he is proved guilty. A medicine—that is, a noxious agent, like a blister, a seton, an emetic, or a cathartic—should always be presumed to be hurtful; it may be sometimes indirectly beneficial. If this presumption were established, and disease always assumed to be the innocent victim of circumstances, and not punishable by medicine, that is noxious agents or poisons, until the contrary was shown, we should not frequently hear the remark commonly attributed to Sir Astley Cooper—more harm than good is done by medication. Throw out opium, which the Creator himself seems to prescribe, for we often see the scarlet poppy growing in the cornfields, as if it were foreseen that wherever there is hunger to be fed there must also be pain to be soothed; throw out a few specifics which our art did not discover, and is hardly needed to apply; throw out wine, which is a food and the vapors which produce the miracle of anesthesia, and I firmly believe that if the whole materia medica *as now used*, could be sunk to the bottom of the sea, it would be all the better for mankind,—and all the worse for the fishes."

He pays his respects to medical schools, teachers, and journals as follows: "Add to this the great number of medical journals, all useful, we hope, most of them necessary, we trust, many of them excellently well conducted, but which must find something to fill their columns, and so print all the new plans of treatment and new remedies they can get hold of, as the newspapers, from a similar necessity, print the shocking catastrophies and terrible murders. Besides all this, here are we, the great body of teachers in the numberless medical schools (year 1860)! Some of us lecturing to crowds who clap and stamp in the cities, some of us wandering over the country like professional fertilizers, to fecundate the minds of less demonstrative audiences at various scientific stations; all of us talking habitually to those supposed to know less than ourselves, and loving to claim as much for our art as we can, not to say for our own schools, and possibly indirectly for our own practical skill. . . . Have we forgotten what is told in one of the books published under our own sanction, that a simple measure of ventilation had saved more than *sixteen thousand children's lives* in a single hospital. How long would it have taken small doses of calomel and rhubarb to have saved as many children? Causes, causes and again causes—more and more we fall back on these as the chief objects of our attention. The shortest system of medical practice that I know of is the oldest, but not the worst. It is older than Hippocrates, older than Chiron the Centaur. Nature taught it to the first mother when she saw her first-born child putting some ugly pebble or lurid berry into its mouth. I know not in what language it was spoken, but I know that in English it would sound thus: "Spit it out!"

Art can do something more than say this. It can sometimes reach the pebble or berry after it has been swallowed. But the great thing is to keep these things out of the children's mouths, and as soon as they are beyond reach, to be reasonable and patient with nature, who means well, but does not like to hurry, and who took nine calendar months, more or less, to every mother's son among us, before she thought he was fit to be shown to the public." . . . He then pleads for the right of speech and tolerance of opinion, as being one of the birthrights of an American. He says: "This Republic is the chosen home of *minorities*, of the less power in the presence of the greater. The history of most countries has been that of majorities—mounted majorities, clad in iron, armed with death, treading down the tenfold more numerous minorities. In old civilizations they root themselves like oaks in the soil; men must either live in their shadow or cut them down. With us the majority is only the flower of the passing noon, and the minority is the bud which may open in the next morning's sun. We must be tolerant, for the thought which stammers on a single tongue to-day may organize itself in the growing consciousness of the time, and come back to us like the multitudinous waves of the ocean on the morrow."

The following sentences are taken from his lecture—Border Lines of Knowledge in Medicine (1861). "The entrance upon a new course of lectures is always a period of interest to instructors and pupils. As the birth of a child to a parent, so is the advent of a new class to a teacher. As the light of the untried world to the infant, so is the dawning of the light resting over the unexplored realms of science to the student. . . . This day belongs, however, not to myself and my recollections, but to all of us who teach, and all of you who listen, whether experts in our specialties or aliens to their mysteries, or timid neophytes just entering the portals of the hall of science. Look in with me, then, while I attempt to throw some rays into its interior, which shall illuminate a few of its pillars and cornices, and show at the same time how many niches and alcoves remain in darkness.

"Science is the topography of ignorance. From a few elevated points we triangulate vast spaces, welcoming infinite unknown details. We cast the lead and draw up a little sand from abysses we may never reach without our dredges. The best part of our knowledge is that which teaches us where knowledge leaves off and ignorance begins. Nothing more truly separates a vulgar from a superior mind than the confusion in the first between the little that it truly knows, on the one hand, and what it half knows and what it thinks it knows on the other."

Of chemistry he says: "It is accomplishing wonders before us every day, such as Arabian story-tellers used to string together in their fables. It spreads the sensitive film on the artificial retina which looks upon us through the optician's lens for a few seconds, and fixes an image that will outlive the original. It questions the light of the sun, and detects the vaporized metals floating around the great luminary—as if the chemist of our remote planet could fill his bell-glasses from its fiery atmosphere. It lends the power which flashes our messages in thrills that leave the lazy chariot of day behind them. It seals up a few dark grains in iron vases and lo! at the touch of a single spark, rises in smoke and flame a mighty Afrit with a voice like thunder and an arm that shatters like an earthquake. The dreams of Oriental fancy have become the sober

facts of our everyday life, and the chemist is the magician to whom we owe them."

From his essay "Some of My Early Teachers" (1882), these sentences are selected: "There are three occasions upon which a human being has a right to consider himself as a center of interest to those about him: When he is christened, when he is married, and when he is buried. Every one is the chief personage, the hero, of his own baptism, his own wedding, and his own funeral." . . . His theme is taken up with the detail of his student days, and so he is the central figure and hero for the hour and feels that he ought to be pardoned for occupying the center of the stage. During his first year as a medical student at Harvard he says: "For during that year I first tasted the intoxicating pleasure of authorship. A college periodical, conducted by friends of mine, still undergraduates, tempted me into print, and there is no form of lead-poisoning which more rapidly and thoroughly pervades the blood and bones and marrow than that which reaches the young author through metal contact with type-metal. *Qui a bu boira*—he who has once been a drinker will drink again, says the French proverb. So the man or woman who has tasted type is sure to return to his old indulgence sooner or later. In that fatal year I had my first attack of author's lead-poisoning, and I have never got quite rid of it from that day to this."

When Holmes was a student the great medical Mecca was Paris, and everybody with a desire to finish up and polish off hastened to the gay French Capital. He describes some of his teachers as follows: "Dupuytren, a square and solid man with a high and full-domed head, oracular in utterances, indifferent to those around him. I do not think Dupuytren has left a record which explains his influence, but in point of fact he dominated those around him in a remarkable manner. You must have all witnessed something of the same kind. The personal presence of some men carries command with it, and their accents silence the crowd about them, when the same words from other lips might fall comparatively unheeded. As for Lisfranc, I can say little more of him than that he was a great drawer of blood and hewer of members. I remember his ordering a wholesale bleeding of his patients, right and left, whatever might be the matter with them, one morning when a phlebotomizing fit was on him. I recollect his regretting the splendid guardsmen of the old Empire—for what? because they had such magnificent thighs to amputate!

Of Velpeau he said: "He had not what is called genius, he was far from prepossessing in aspect, looking as if he might have wielded the sledge-hammer rather than the lancet, but he had industry, determination, intelligence, character, and he made his way to distinction. A good sound head over a pair of wooden shoes is a great deal better than a wooden head belonging to an owner who cases his feet in calfskin, but a good brain is not enough without a stout heart to fill the four great conduits which carry at once fuel and fire to that mightiest of engines."

His description of Broussais makes him appear like a character Balzac or Dickens might have created. "He was in those days like an old volcano, which has pretty nearly used up its fire and brimstone but is still boiling and bubbling in its interior, and now and then sends up a spurt of lava and a volley of pebbles. His theories of gastroenteritis, of irritation and inflammation as a cause of disease, ran over the fields of medicine for a time like flame over the grass of the prairies. The way in which that knotty-featured, savage old man would bring out the word irritation—with rattling and rolling reduplication of the resonant letter *r*—might have taught a lesson in articulation to Salvini. But Broussais' theory was languishing and well nigh become obsolete, and this, no doubt, added vehemence to his defense of his cherished dogmas.

"Old theories and old men who cling to them must take themselves out of the way as the new generation with its fresh thoughts and altered habits of mind comes forward to take the place of that which is dying out. This was a truth which the fiery old theorist found it very hard to learn, and harder to bear, as it was forced upon him; for the hour of his lecture was succeeded by that of a younger and far more popular professor. As his lecture drew towards its close, the benches, thinly sprinkled with students, began to fill up; the doors creaked open and banged back oftener and oftener, until at last the sound grew almost continuous, and the voice of the lecturer became a leonine growl as he strove in vain to be heard above the noise and footsteps."

He speaks of Louis and his work in the autopsy room. He said he was a most skillful diagnostician and a great pathologist, but not a therapeutist, and it was a fad for the students of that day to follow "science" instead of pills and powders, and they learned one thing in the words of Louis, and that was how very large a proportion of diseases got well of themselves without any special medication. He admits that had he followed Trousseau instead he would have had more remedies and "sure cures" at his disposal. Here the seeds of therapeutic nihilism and infidelity were sown—and yet he naïvely adds that "it is not of the slightest interest to the patient to know whether three or three and a quarter cubic inches of his lung are hepatized. His mind is not occupied with thinking of the curious problems which are to be solved by his own autopsy—whether this or that strand of the spinal marrow is the seat of this or that form of degeneration. He wants something to relieve his pain, to mitigate the anguish of dyspnea, to bring back motion and sensibility to the dead limb."

He mentions many other distinguished and well-known names, and has this passing word for one: "I think life has not yet done with the vivacious Ricord, whom I remember calling the Voltaire of pelvic literature—a skeptic as to the morality of the race in general, who would have submitted Diana to treatment with his mineral specifics, and ordered a course of blue pills for the vestal virgins."

His address to the "Young Practitioner" is full of good things and ought to be read in full. It is almost a crime to omit a single sentence, but space forbids. "Your diploma seems very broad to-day, but it begins to shrink from this hour like the *Peau de Chagrin* of Balzac's story. Do not worry about it, for all the while there will be making for you an ampler and fairer parchment, signed by old Father Time himself as President of that great university in which experience is the one perpetual and all-sufficient professor. Your present plethora of acquirements will soon cure itself. Knowledge that is not wanted dies out like the eyes of the fishes of the Mammoth Cave. You are now fresh from the lecture-room and the laboratory. You can pass examinations in all the branches which the men of large practice all around would find a more potent sudorific than any in the Pharmacopeia. The young man knows the rules—but the old man knows the *exceptions!* . . . New ideas build their nests in young men's brains. . . . Revolutions are not made by men in spectacles. . . . I had rather be cared for in a fever by the best taught among you than by the renowned Fernelius or the illustrious

Boerhaave, could they come back to us from that better land where there are no physicians needed, and, if the old adage can be trusted, not many within call. . . . By the oath of Hippocrates, the practitioner of ancient times bound himself to enter his patient's house with the sole purpose of doing him good, and so to conduct himself as to avoid the very appearance of evil. Let the physician of to-day begin by coming up to this standard, and add to it all the more recently discovered virtues and graces."

"There are personal habits of less gravity, but of great value. A man, who may be called at a moment's notice into the fragrant boudoir of suffering loveliness, should not unsweeten the atmosphere with the reminiscences of extinguished meerschaums. He should remember the sick are sensitive and fastidious, that they love the sweet odors and the pure tints of flowers, and if his presence is not like the breath of the rose, if his hands are not like the leaf of the lily, his visit may be unwelcome, and if he looks behind him he may see a window thrown open after he has left the sick chamber. I remember too well the old doctor who sometimes came to help me through those inward griefs to which childhood is liable. . . . Before him came a soul-subduing whiff of ipecacuanha, and after him lingered a shuddering consciousness of rhubarb. He had lived so much among his medicaments that he had at last become a drug himself; and to have him pass through a sick chamber was a stronger dose than a conscientious disciple of Hahnemann would think it safe to administer.

"One practical hint may not be out of place here. It seems to be sometimes forgotten by those who must know the fact, that the tongue is very different, anatomically and physiologically, from the stomach. Its condition does not in the least imply a similar one of the stomach, which is a very different structure. A silversmith will for a dollar make a small *hoe*, of solid silver, which will last for centuries, and will give a patient more comfort, used for the removal of accumulated epithelium and fungus growths which constitute the "fur," than many a prescription with a split-footed ℞ before it, addressed to the parts out of reach. . . . I have seen an old account-book in which the physician charged an extra price for gilding his rich patient's pills. If all medicaments were costly, and the expense of it always came out of the physician's fee, he would naturally think twice before he gave an emetic or cathartic which evacuated his own pocket, and be sparing of the cholagogues that emptied the biliary ducts of his own wallet, unless he was *sure* they were needed.

"Gratitude frequently is one phase of a morbid condition. Many patients are very grateful, and often when we have cured them of their diseases, we likewise have cured them of their gratitude.

"You will remember, of course, always to get the weather-gage of your patient. I mean to place him so that the light falls on his face, and not on yours. It is a kind of ocular duel that is about to take place between you. You are going to look through his features into his pulmonary and hepatic and other internal machinery, and he is going to look into yours quite as sharply to see what you think about his probabilities for time and eternity. No matter how hard he stares at your countenance he should never be able to read his fate in it. It should be cheerful as long as there is hope, and serene in its gravity when nothing is left but resignation. The face of a physician, like that of a diplomatist, should be impenetrable. Nature is a benevolent old hypocrite; she cheats the sick and the dying with illusions better than any anodynes. If there are cogent reasons why a patient should be undeceived, do it deliberately and advisedly, but do not betray your apprehensions through your tell-tale features.

Holmes makes this sly dig at those Uriah Heeps, fakirs and invisible handwashers in the profession: "We had a physician in our city whose smile was commonly reckoned as being worth five thousand dollars a year to him—in the days, too, of moderate incomes. . . . Some shrewd old doctors have a few phrases always on hand for patients that will insist on knowing the pathology of their complaints without the slightest capacity of understanding the scientific explanation. I have known the term 'spinal irritation' serve well on such occasions, but I think that nothing on the whole has covered so much ground, and meant so little and given such profound satisfaction to all parties as the magnificent phrase, 'Congestion of the portal system.' . . .

"The life of a physician becomes ignoble when he suffers himself to feed on petty jealousies and sours his temper in perpetual quarrels. You will be liable to meet an uncomfortable man here and there in the profession—one who is so fond of being in hot water constantly that it is a wonder all the albumen in his body is not coagulated."

Before finishing this article I would like again to refer to the editorial of the Medical Record which was quoted in the beginning, and correct an apparent error and wrong to the memory of Dr. Holmes. The editorial says in reference to his paper on the "Contagiousness of Puerperal Fever": "There was an abundance of material, and in the essay which followed there was an array of facts that should have left no doubts in the mind of the reader, that the disease was communicable. But, like all revolutionary discoveries, it was received with incredulity, etc., the bitterest opponents being Hodge of the University of Pennsylvania, and Meigs of the Jefferson Medical College. Holmes was *no fighter*, and, though he continued to teach medicine for many years, his heart was more inclined to the gentler art of poesy, and he made no strenuous effort to uphold his views, etc." The facts do not show that he tamely submitted. He *was* a fighter. His written word says so. The issue was joined in the affirmative statement by Holmes: "The disease known as puerperal fever is so far contagious as to be frequently carried from patient to patient by physicians and nurses" (1843); and opposed by Professor Hodge (1852), who said: "The result of the whole discussion will, I trust, serve . . . to divest your minds of the overpowering dread . . . that you can *ever* convey, in any possible manner, a horrible virus, so destructive in its effects, and so mysterious in its operations as that attributed to puerperal fever;" also further fortified by the negative views of Meigs (1852): "I prefer to attribute them to accident, or Providence, of which I can form a conception, rather than to a contagion, of which I cannot form any clear idea."

In his essay of 1843 he assails the objections of his opponents with all the intensity and earnestness possible, and when he had finished it he was afraid that he had been too severe. "I have no wish to express any harsh feeling with regard to the painful subject which has come before us." He rewrote his theses and added more uncontrovertible facts in 1855, and in his well-known address, "Currents and Counter Currents," delivered in 1860, he said: "The causes of disease have been less earnestly studied in the eagerness of the search for remedies. Speak softly! Women have been borne out from an old-world hospital, two in one coffin, that the horrors of their prison house might not be known, while the very men who were discussing the treatment of the

disease were stupidly conveying the infection from bed to bed, as rat-killers carry their poisons from one household to another. Do not some of you remember that *I have had to fight this private-pestilence question against a skepticism* which sneered in the face of a mass of evidence such as the calm statisticians of the insurance office could not listen to without horror and indignation?" (Italics are mine.)

This does not sound like one indifferent; it is not feeble language. It is framed in the strongest words he could match up, and he fought the resourceless opposition with all his might and strength. When Meigs said, "I prefer to attribute them to accident, or Providence," he talked more like a theologian, who has always been willing to dump all his doubts and unsolved problems of life in the front yard of Providence. The rubbish which has been piled up there by men of that type has been enormous, and I am afraid that it is diminishing but too slowly, yet science and honest thinkers have done a whole lot to keep that pile down.

Holmes died in 1894, but long before he left his active work he had the supreme satisfaction of seeing his views as a young man at thirty-four made good in all the clinics and lying-in hospitals in Europe. As early as 1882 Scanzoni and Bumm at Wurzburg, Credé at Dresden, Breisky at Prague, among many others, were already sending out glowing reports of the marvelous life-saving practice of antiseptic midwifery.

THE SERUM TREATMENT OF HAY FEVER.

By CHAS. H. KNIGHT, M.D.,

NEW YORK.

Serum therapy is an attractive subject of study. A therapeutic resource based on scientific principles and promising definite results is certainly most alluring. At first glance its use in hay fever would seem illogical, since in this disease we are dealing with a neurotic disorder, complicated, possibly, by an intranasal anomaly, and apparently excited by some irritant conveyed by the inspired air. How is it possible for such an affection to be influenced by merely local treatment? The question seems to have been answered by Professor Dunbar of Hamburg, who has succeeded in extracting from certain grasses and cereals a toxin entirely free from mechanically irritating qualities, but capable of exciting the characteristic phenomena of hay fever in those susceptible. Thus the old "pollen theory" of etiology, in accordance with which the pollen granules themselves were supposed to induce the local derangement, is supplanted by the view that the source of irritation exists in a toxalbumin residing in the pollen. According to Liefmann, about 700 pollen grains are, on certain days, inhaled with each cubic meter of air. The significance of this fact is apparent when taken in connection with the statement that two or three pollen grains contain enough toxin to cause an attack of hay fever. In an interesting essay, entitled "Hay Fever: Recent Investigation on Its Cause, Prevention, and Treatment," R. A. Glegg of Edinburgh quotes Kammann of the Hygienic Institute at Hamburg to the effect that the potency of the toxic proteid obtained from the pollen is such that one forty-thousandth of a milligramme will cause itching and redness of the conjunctiva in a hay-fever subject, lasting several hours. Thus the evidence that pollen or its toxin is at least one of the causes of hay fever seems to be incontestible. By a series of animal inoculations Dunbar has also produced an antitoxin which allays the disturbance created by the toxin, and which is claimed to dispel or modify the symptoms of hay fever. The process of deriving an antitoxin from a toxin by combining a vegetable extract with an animal product is without precedent, and, in the minds of some, envelops the whole proposition in a cloud of suspicion. The immunity conferred by the antitoxin is not permanent, but lasts from six to twenty-four hours, when the application must be renewed. Observations made up to the present time indicate that a given toxin may be poisonous to one individual, but not to another, and that a given antitoxin may exert control over various toxins. Some discredit is thrown on the latter assumption by the disappointment met with by A. W. MacCoy in his use of the 1904 serum, after a series of brilliant successes in the season of 1903. He explains his failures by the fact of having used a serum of excessive strength and derived from a source not suited to victims of the disease in this country. It seems to be conceded that the antitoxin proper for use in our autumnal hay fever must be obtained from the golden rod and rag weed. MacCoy's confidence in the remedy is so firm as to lead him to the conclusion that, "with sera of fixed units of strength adapted to the varying conditions of the inhabitants of the American continent, the immunization and cure of all cases of hay fever is, practically, an accomplished fact." His most decided results were seen in the autumnal form of hay fever, while Emil Mayer declares the serum efficacious in the vernal, but not in the autumnal variety. On the other hand the results obtained by Mackenzie, at Johns Hopkins, were absolutely negative, and he is therefore incredulous as to the efficacy of the serum. He still maintains the opinion expressed at the last meeting of the American Laryngological Association and published in the volume of Transactions for 1905. He calls attention to the curious fact that the rose with an unrivaled reputation as a disturber of the Schneiderian membrane, has thus far not been persuaded to yield a toxin. In striking contrast with the foregoing is a statement made by H. W. Loeb in a recent paper to the effect that the best results with the serum have been obtained in so-called "rose fever," or "German hay fever." The observations of the latter authority seem to have been made with exceptional care and thoroughness. He found that most annoying symptom, itching of the eyes, as well as that of the nose and palate, almost invariably relieved. The rhinorrhea, nasal stenosis, and sneezing were uniformly overcome, while in every case of asthma the symptoms were much benefited. It surely would be unreasonable to ask more than this, and we may readily appreciate the enthusiasm of this writer.

Serum for hypodermic injection and in fluid form has been almost entirely abandoned. The latter is unstable and the former is apt to be followed by excessive local reaction. In powder, which seems to have been generally adopted, no disturbance follows nasal insufflation beyond, in some cases, temporary aggravation of the local irritability. This is seen to subside after persistence with treatment. It sometimes happens that the onset of the attack is so abrupt and the nasal stenosis so extreme that it is difficult to introduce the powder. In such case it has been proposed to retract the swollen tissues with cocaine or adrenalin. This practice is not to be recommended. If Dunbar's antitoxin has the virtues attributed to it it should be able to stand alone. The use of adjuvants confuses therapeutic effects and may deprive the serum of some of the credit to which it is entitled.

The following figures are compiled from the reports of 81 physicians in various parts of the country.

The total number of cases was 219. Of these there were

Effectively benefited	114, or 52	per cent.
Partially "	66, or 30	"
Not "	39, or 18	"

Of the total number of cases 68 had asthma, and of these there were

Effectively benefited	30, or 44	per cent.
Partially "	26, or 36	"
Not "	13, or 20	"

These statistics correspond closely with those of Luebbert and Prausnitz, and others.

In a personal letter just received from Professor Dunbar there are several points reference to which may be of interest. For his kindness in placing it at my disposal, as well as for a collection of literature bearing on the subject, I wish to express my obligation. He mentions three possible causes of failure with the serum:

1. "The patient does not react to pollen toxin, and is therefore also indifferent to the antitoxin." In other words, if the antitoxin is ineffective the case is not an example of genuine hay fever. This may seem like "begging the question." At the same time we all use tentative treatment in other cases of doubtful diagnosis; then why not pollantin in hay fever? The toxin itself is said to be a reliable diagnostic test. Its effects are so promptly counteracted by the antitoxin that it may be used for this purpose with confidence and safety. It should be freshly prepared and highly diluted—1 to 50,000—to be gradually increased in strength if no results follow.

2. "Some patients are irritated by normal blood serum, and therefore also by pollantin," since the irritating substance and the antitoxin exist together in the globulin and cannot be separated. In spite of the unpleasant effects—sneezing, etc.—the use of the remedy should be continued. It is found to be an advantage to apply it in extremely small quantity and diluted with sugar of milk (1:4). From personal experience Dunbar asserts that this comparatively transient irritation is much more endurable than a continuous attack of hay fever. Experiments now in progress give hope of obtaining a preparation free from these objections.

3. "Many patients use far too much of the pollantin." The contents of a vial should last eight to fourteen days. (In his own case half a tube carries him through the season.) It is difficult to restrain the extravagance of those who think that if a little does good, a great deal must do more good. Yet this suggestion as to dose is believed to be of the utmost importance. In the words of Dunbar, "Use pollantin in minute quantities and start the treatment before the attack begins."

In observing a disease so baffling and protean as hay fever we encounter many confusing factors. The psychic element in many cases should not be overlooked, since otherwise we may be led to most erroneous conclusions as to the effect of remedies. We are all familiar with the artificial rose experiment related by Mackenzie of Baltimore. Another case in illustration has recently been reported by Guest of Louisville, in the person of a relative, who, having tried every known remedy for his hay fever without avail, in despair resorted to Christian Science. At about the time his letter of application for "absent treatment" should have reached its destination his symptoms began to abate, and the next day had practically disappeared. While he was comparing the present result with those under the ministrations of orthodox medicine, to the keen disparagement of the latter, he received a message from the priestess of the faith, announcing that she was away when his letter arrived, but would begin treatment at once. His idol having been shattered, all the hay fever symptoms recurred with original intensity. Doubtless similar examples could be supplied indefinitely. Suggestion, hypnotism, and faith-healing may, perhaps, find in hay fever a profitable field for their exploits.

There is danger that the simplicity of its administration may lead to general use of the remedy without competent advice and to consequent neglect of serious nasal abnormalities. A momentous incidental consideration is that the surgeon is thereby robbed of his fee. The etiological importance of these nasal conditions has been greatly exaggerated, and the original views and practice of the propounders of the "nasal origin" of hay fever have been subjected to radical modification. No doubt the suffering of the patient may be much mitigated by judicious nasal treatment, but in many cases the actual cure of the disease is as remote as ever.

From a study of reports on this subject hitherto made, a final decision as to the value of the treatment does not as yet seem warranted. The discrepancies and sources of error are so manifold that it is by no means easy to solve the problem. One observer carefully follows directions as to hygiene and régime, while another disregards them entirely. One employs various agents in conjunction with the serum, while another discards all other medication; one records a dismal list of failures, while another claims success in more than half his cases. Lack of uniformity in the preparation and use of the remedy, as well as in the general management of the patient, may, perhaps, explain in part the prevailing diversity of opinion. It seems fair to require an observance of the ordinary laws of health, even if we do not go so far as to adopt the special precautions, such as excluding the night air during sleep, etc., insisted upon by Dunbar. As intimated by Ingals, many of our patients would do well without medicine if they were to follow the stringent hygienic measures enjoined. The strength of the serum and the sources whence it is obtained, no less than care and moderation in its administration, are important points. From the mass of experience and literature being accumulated, we may expect soon to arrive at a just estimate of this new claimant for favor. In the meantime experiments with the serum may be continued with the assurance that at least it does no harm, even though it gives results no better than those acquired by other methods.

HUMAN BLOOD PRESSURE AND PULSE S AFFECTED BY ALTITUDE.*

By CHARLES FOX GARDINER, M.D.,
and HENRY W. HOAGLAND, M.D.,
COLORADO SPRINGS, COLO.

The pressure of the blood in the arteries of man has been made the subject of much speculation and study from early times; the force of our arterial blood current against our vessels both in health and disease offers an interesting and important symptom, and one that has been observed by the method of noting the pulse at the wrist for centuries. It is, however, only in recent years that careful and systemic study of the force of the blood in its circulation through the body has been undertaken. The finger on the radial artery at the wrist, while valuable, and in the hands of experienced men of much practical utility in determining diseased conditions or changes in blood pressure, is after a a crude

*Read before the American Climatological Association, 1005.

and uncertain method, depending entirely upon the tactile sense of the observer, and while the number of beats per minute can be counted, and the volume of blood and the condition of the artery noted, it is a method only approximately exact; too much depends upon the factor of personal equation in the observer. Considerable advance was made when instruments were devised by which a needle was made to move by the impulse at each pulse beat of the artery, and a graphic record traced on a moving slip of paper. This method was also found to have its limitations, and in recording pressure of blood not always exact. A decided advance has been made in the last few years in using several forms of apparatus depending upon the principle of mechanical constriction of limb or finger, and using the pressure of the blood constricted in this manner to elevate some form of index as a slender column of mercury in a graduated tube, or by a needle on a dial. In this manner the pressure can be taken in man without the errors of the older methods, and a standard established for a large number of human beings under different conditions. With the use of these more recent instruments of precision it has been made possible for us to measure the force of the blood stream in certain diseases, and in health. Many peculiar effects are noted from the use of drugs, exercise, and mental disturbances on the delicate mechanism of the circulation.

It was therefore to take advantage of this comparatively new means of measuring the force of blood in the arteries that some three years ago we decided to test the effect of the altitude in Colorado on the blood pressure in human beings. Some work had been done on this subject in Europe, but the reports differed in several essential points. In Mexico two observers also have made a report, but with instruments of older date only. As to the general impressions on this subject, it has been observed that as at a considerable height above the sea some individuals suffer from a feeling of fullness in the head, with hemorrhages from the nose, etc., the blood pressure at these elevations must be increased, and the serous symptoms occurring at altitude, such as rapid pulse, breathlessness, dizziness, and even fainting in otherwise healthy people, have very clearly shown a pronounced effect from altitude upon the circulatory apparatus in human beings. What effect this had on the actual tension of the blood was more or less a disputed point. This is, however, a point of some importance—to definitely determine the effect of altitude upon the heart and blood vessels, and it has seemed to us well worth the effort. There are in the United States at present a number of cities at a considerable elevation. We have a large and rapidly-growing population in our Western States on both sides of the Rocky Mountain ranges that live under an air pressure on their bodies of 20 per cent. less than that air pressure would be at the sea level, or about twenty-four inches of mercury barometer pressure as compared to thirty at sea level. Such a difference represents about three pounds to each square inch of the human body. It is true that in most cases the effect of this difference in surface pressure is met promptly and effectively by the wonderful adaptation of our nervous and circulatory mechanism, so that the physiological disturbance is slight or absent. It is well known that there are cases that do not adapt themselves so rapidly, and some that never do, while in certain diseases affecting the heart, this diminished pressure is apt to prove a dangerous factor.

Exactly how such effects are produced from the altitude of our elevated regions has not been satisfactorily explained. Any light on this obscure subject cannot fail to be of value, as it would tend in time to place the study of altitude effects upon a definite scientific foundation, and, what is of more importance, enable the physician to deal with such effects during disease, in an intelligent manner.

It was therefore with this aim in view that we began a series of investigations in blood pressure in Colorado. We only selected healthy individuals to experiment with, as it was first necessary to establish a normal mean pressure for altitude, as has been done at sea level, and not pressure subject to the irregularities or fluctuations produced by diseased conditions, however slight. We were fortunate in having unusual opportunities for this series of investigations. We were in a city of 30,000 inhabitants, at an elevation of 6,000 feet above the sea. A well equipped scientific laboratory in the new science building of Colorado College was, by the kindness of President Slocum, placed at our disposal, while the Professor of Physics, John Cutler Shedd, Ph.D., and of Biology, Professor Edward C. Schneider, Ph.D., gave us every aid in their power. Among the college students we could choose any number for experiment, and they kindly offered their services at any time. Five miles away by electric cars the Pike's Peak Railroad took us easily and without exercise to the summit of Pike's Peak, 14,000 feet altitude, while on the summit a stone building offered us all the advantages as a shelter from cold or wind, so necessary in conducting delicate scientific experiments. The technique was as follows:

The instruments used were two Riva-Rocci, with 5 c.c. cuffs, a new Janeway with a 12 c.c cuff, and an instrument modified from the Janeway with a 12 c.c. cuff. The individual examined was at rest in a sitting position, cuff on left arm, all muscles relaxed, and all disturbing factors eliminated. Measurements were made several times in each case and by four observers and with three instruments to obviate personal differences in technique. The average in these measurements was then taken as the result for that case, also each case was measured on several occasions, during several days. The time of day was noted to obviate diurnal variations. By this care we feel reasonably sure of our normal mean pressure in each case.

The pulse rate was taken with the same detail. We divided the work into groups.

Group No. I.—Average pulse and blood pressure in men and women of all ages, resident at 6,000 feet altitude for over one year.

In averaging a large number of individuals we came to the conclusion that as a rule blood pressure was slightly lower than that given as the normal at sea level, while the pulse rate did not show the increased rapidity said to be present in altitude dwellers.

Group No. II.—Average pulse and blood pressure in men who had lived at 6,000 feet altitude for over twenty-five years.

Fifty males were now measured who had lived at least twenty-five years at 6,000 feet altitude, and a number thirty, in two cases forty-four years. We found in these cases that considering age the blood pressure was certainly lower than that given for sea level [2] while the pulse was normal. Evi-

dently, prolonged residence at 6,000 feet altitude had not increased the blood pressure in these individuals; but caution should be used in taking too much as proved from our work in this group of experiments. These individuals possibly represent a survival not only from death of a certain number during the twenty-five or more years, but from the fact that at this altitude any disease of heart or arteries is very likely to cause the patient at once to seek a different and generally less elevated climate, leaving survivors who represent a special class, and our observations were on this special class.

Group No. III.—Effect of muscular exertion upon college men.

First determining the normal blood pressure, we then had our men exercise violently at football, running, etc., etc. The result differed very little from similar experiments conducted near sea level. Pressure was as is usual increased by muscular work at first and at last returned to normal.

Group No. IV.—Effect upon blood pressure and pulse upon twenty-two men and women taken from 6,000 to 14,000 feet.

The individuals comprising this group were tested a number of times and their average pulse and blood pressure estimated at 6,000 feet. They were then taken up to 14,000 feet on the Pike's Peak Railroad in a private car without any muscular exertion, were measured while in the car on the summit, and again after three and one-half hours at 14,000 feet. Some returned sooner to 6,000 feet, and all were again tested on their return to 6,000 feet to note any possible effects of the change in altitude. While work on this group was interesting and showed some peculiar phases of blood and blood pressure due to changes in altitude, we did not feel that our results were accurate, or our averages as scientific as we had determined to have them. The personal element as a factor entered too largely into the calculations, while the marked differences in age, occupation and mental disturbances were not in our opinion sufficiently guarded against. We therefore for another year perfected ourselves in technique and tested a large number of people under different conditions, and in June, 1904, we felt we could venture on some reliable work.

Group No. V.—Effect upon pulse and blood pressure in twenty two college men taken from 6,000 to 14,000 feet, and the effect of three and one-half hours at 14,000 feet.

We selected twenty-two students from Colorado College of nearly the same age and occupation, and for some weeks in the Science Laboratory estimated their individual and average pulse and blood pressure. Our normal pressure obtained in this way we compared with the work of O. Z Stephens, M.D., of Chicago, Ill., on twenty-two college men. We found that our group at 6,000 feet altitude had a lower blood pressure and a slower pulse rate, blood pressure average being 126 mm. at 6,000 feet, 130 mm. at sea level; pulse at 6,000 feet, 80, at sea level, 82. The men were now taken by special engine and private car to the summit of Pike's Peak, and on arrival were taken to a room in the hotel; all excitement and exertion were thus avoided. They were then tested, using same technique as employed in the laboratory at 6,000 feet. Results showed an average pulse of 86 and blood pressure of 121, a gain in pulse rate of 15 and a reduction of blood pressure of 5 mm.

After three and one-half hours at 14,000 feet, the men were again examined. The pulse rate had now gone up to 99 per minute, and the blood pressure fallen to 118 mm. Some exercise, such as walking, had, however, been taken by all the individuals of this group during the three and one-half hours at 14,000 feet altitude, and should be remembered in estimating results in this series. No doubt an equilibrium is established in time, and the pulse rate and blood pressure return more nearly to a normal standard. How long this takes probably varies in different individuals. From examination of some employees at the summit who had lived at 14,000 feet altitude for two months, we judge this equilibrium does not take more than a few days, but that the tension after compensation has taken place is always lower than the tension of that individual would be at sea level or at a lower altitude, in almost all cases.

The men were examined during several days after their return from this trip and nothing unusual was noted.

The full significance of this fall in blood pressure due to altitude, in young healthy adults, we cannot at present estimate. It is a complex subject and requires more detailed study from many points of observation. It is, however, interesting to note the difference between the position of the body as affecting blood pressure, and the effect of altitude. If the body is placed in the prone position, the heart beats more slowly, while the blood pressure is increased. In ascending to a high altitude, the heart beats faster and the blood pressure is lowered.

We found a rough ratio between pulse rate and blood pressure: the more rapid the pulse, the lower the blood pressure. It was also noted that when a pulse rate was but little affected by an altitude of 14,000 feet, the blood pressure was also more constant; that cases of mountain sickness were accompanied by a fall in blood pressure and a rapid pulse rate.

From this work upon the pulse and blood pressure we feel justified in offering the following suggestions: Although we found the average pressure of the blood was not lowered more than from 8 to 10 mm. of Hg. in a diminished atmospheric pressure of 8,000 feet altitude, and that this change in pressure in the blood is a small one in healthy young adults, it can easily be seen that such a change from the normal, continued for a considerable time, especially in many diseased conditions, would be a positive and possibly a serious interference with the mechanism of the human circulation, an interference that under given conditions might be a strong influence either for good or ill.

In cases in which (due to changes in the heart muscle) the blood tension is abnormally lowered, a further reduction would be dangerous, and in such cases, taking the tension at sea level, one could possibly determine the danger of the effect of altitude in further lowering it; while in other cases, as in some forms of aneuryisms, with high tension, and in some forms of valvular disease of the heart, the effect of altitude would be decidedly beneficial, and such cases have indeed come under the observation of the writers. It must, however, be remembered that the effect of altitude upon the circulation of the blood in human beings is at best a complex subject. We know that in healthy persons the arterial pressure in the main blood vessels is lowered in response to the diminished atmospheric pressure upon the body, as the elevation above the sea is increased, but we know very little as yet as to the effect of diminished atmospheric pressure upon the venous system. It is

highly probable that the right side of the heart and venous system play a more important part in the phenomena of altitude effects than we are at present in a position to verify. The smaller, or capillary blood vessels, on the surface of the body, and on exposed mucous membranes, are enlarged when atmospheric pressure is diminished, and this is seen by examination of the blood, and by bleeding from mucous surfaces. As to a resulting lowering of pressure in the capillaries of internal organs due to the external hyperemia, we as yet know nothing positively, and it is by the further study of the pressure in the venous system that altitude effects upon human circulation will yield the most valuable results in the future.

We want to acknowledge with many thanks the kindness of Professor Slocum for the use of the Science Building of Colorado College, and of Professor Snyder, Dr. Dennis, and Dr. Scully for valuable assistance, and of Mr. Sells of the P. P. R. R. for many courtesies extended, and of all who kindly submitted to being tested.

Since writing the above Dr. H. W. Cook, who modified the Riva-Rocci instrument for this country, has been in Colorado with his own instrument, and verified our findings on blood pressure at this altitude conjointly with us.

INEBRIETY OFTEN A FORM OF MORAL INSANITY.

By T. D. CROTHERS, M.D.,
HARTFORD, CONN.
SUPERINTENDENT WALNUT LODGE HOSPITAL.

Moral insanity is a disease marked by a low sense of right and wrong, and by conduct which does not recognize the rights of others, or duty and obligation to any one. The ethical sense and consciousness of the relation to others, of truthfulness, of honesty, of respect for the good and true, for law or for the opinions of others, are enfeebled or wanting altogether.

In inebriety these symptoms of moral defect are common, no matter what the conditions and standing of the person may be. It seems to follow the poisoning from alcohol, and in some cases very markedly. Two classes appear prominently, one with heredity and the other apparently acquired. Wherever there is a marked history of heredity, of alcoholic parents, or of neurotic degenerate ancestors, a feeble or deficient consciousness of right and wrong is found. Alcohol used continuously retards growth, diminishes vitality, and prevents development. Drinking parents have deficient vitality and are unable to transmit to the next generation full normal vigor. The last and highest formed element of brain power—consciousness—is the first to suffer from alcohol. Hence drinking parents seldom have children with full normal consciousness, and ethical development. This faculty will be wanting or very feebly developed. This is the rule to which the exceptions are rare. This defect may be associated with much intelligence and intellectual capacity and power to conceal this condition

A man prominent in the political world is in private life devoid of all sense of justice, of right and wrong, and duty to others. He is untruthful and dishonest, and, when his own interests are in conflict, will sacrifice any person or principle to gain his ends. His parents were wine dealers and drinkers, both of them waiting on customers over the bar. Only one child grew to manhood and entered politics as a trade. He is temperate, but a moral paralytic, or a moral maniac with capacity to conceal this condition A man who became one of the great swindlers and forgers of the day, but who was able to keep out of prison by intrigue and cunning, came from drinking parentage. To his associates he is known as without any sense of duty and obligation to any one, and is a literal Bedouin. That these conditions are due to inheritance is apparent from the following: A boy with excessively alcoholic parents was taken in infancy and educated in the most careful way. All the higher faculties were cultivated to an unusual degree, and he entered the church as a brilliant clergyman. He was found to be untruthful in regard to himself, suspicious of others in matters of personal reputation, and grasping even up to the border of theft on many matters. The collections in the church had to be kept out of sight and always suffered if they passed through his hands. He became involved in spreading scandal, and seemed oblivious of the danger of such conduct, and broke up the church by his irregularities. For ten years, until his death, he was in continual trouble with every church he was associated with. Here the evidence was clear that he had inherited defective consciousness, which no training or surroundings could overcome.

In cases where inebriety has been acquired by accident, contagion of surroundings and conditions of living, these moral insanities vary widely and are not so general, but are confined to particular things.

In one instance excessive untruthfulness and dishonesty in all business relations was associated with sympathetic tenderness to associates. In another, intense suspicion and doubt of the honesty of others was associated with excessive desire to be truthful.

Another individual was intriguing, secretive, treacherous, and uncertain in his talk and conduct, and yet lived a moral, upright life. These are examples almost infinite in variety and manifestation, and all show profound changes in the moral faculties. The more common forms are illustrated in this case: A. B., a business man of good reputation and standing in the community, began to drink after a protracted illness from typhoid fever. Two years later he was an inebriate. His mind continued bright and clear, but his character changed. He was deceitful, suspicious, and slanderous. He thought his sons and clerks were robbing him, and that his wife was in league with them. He had his books examined by an expert and was in doubt when they were found correct. He told falsehoods about his business and family, and grew more and more egotistical about his mental capacity to reason and decide on all matters. He was harsh and tyrannical to his wife at times, lost all pride of character in the community and sense of duty to others. He was exacting to have everything done for his own interests, and oblivious

of others and their feelings and tastes. As a patient he was intensely selfish and grasping, even to theft; was fawning and obsequious, promising everything and doing the opposite. He imagined evil of everyone and told malicious stories without any foundation, then denied them. He was always reporting others as doing wrong, and supposed everyone to have only the basest motives. He stopped drinking, but thought all others drank secretly. This man left the asylum and is yet sober after some years, but is morally insane.

In the summary of the common symptoms following the use of alcohol, untruthfulness, or a low respect for their word, is most prominent. A man who previously took pride in the correctness of his promises and statements will become indifferent to his word, whether true or false. A man previously honest and trustworthy will be found doing dishonest things, cheating persons, taking advantage in little matters, and failing to act fairly in the interest of himself or others. Then follows suspicion of motives and conduct, doubting the honesty and purity of persons. This deepens into delusions of intrigue and deception of others, extreme pessimism and doubt of everything, or a state of mind follows, in which the distress of others is pleasing. Recklessness in the use of money, throwing it away without motive or purpose, or extreme parsimony to hoard it, and grasping selfishness, equally unreasonable, are common. As in other insanities, exaltation of the ego follows, and intense confidence in themselves and their power of reasoning and ability to do anything possible is present.

Many persons who exhibit all these symptoms appear to be but little changed in other respects. They carry on business, seemingly make good plans and execute them, and appear to casual observers the same. These insanities seem to concentrate into particular lines or ranges of thought. In one case an inebriate lawyer doubted the honesty of everyone and thought no one was pure or had good motives, and yet he acted rationally on all other matters. In another case a teacher, who had drunk many years, became a secret thief, purloining everything which he fancied, and when likely to be detected restoring it in some mysterious way.

He appeared and talked honestly, and yet when not observed took advantage of every opportunity to appropriate anything that came in his way. A number of cases of inebriates have been reported where this kleptomaniac impulse took on certain peculiar forms. Thus one man when drinking stole Bibles, another jewelry, and when discovered gave it up freely. One man stole washtubs. A woman inebriate always took aprons and towels; another man stole soap, and so on.

The most unusual and unreasonable things were taken, concealed, and given up freely without any sense of the nature of the acts. One class of inebriates exhibits this insanity in malicious slander, another in extreme suspicion, others in vindictiveness to resent real or imaginary evils, others in immorality and impurity of act and thought. Many of the chronic cases exhibit all these phases in one. The oft-repeated expression that "inebriety is criminality," is true in a general sense, when criminality is understood as a course of conduct in which duty, right, and obligation to others are ignored. The inebriate has physically defective senses; he is not able to adjust himself to the outside world correctly, because his knowledge of its relations is imperfect. His power of reasoning is also deranged, because the impressions from without are faulty and the integrity of the normal action of the nervous system is impaired.

The coarser lesions are well recognized and can be traced in all cases. Beyond this conduct indicates the higher moral defects and changes. Physical changes, as loss of pride, of character, of honor, respect for the truth, of duty to others, low motives or no motives, extreme pessimism, are the first and common changes which lead up to criminal acts. The paralyzing action of alcohol is first seen on the moral brain of consciousness in the dullness and defective workings of the higher functional activities. The change observed when a man is under the influence of spirits is vaguely called the removal of the restraint of reason and dominance of the animal impulses—the brute triumphing over the real man. In reality it is palsy of the consciousness, a cutting off of some part of the higher brain, and consequent confusion of the lower brain and its workings.

Impressions and their meaning are confused and obscure; the higher relation of events and conditions of life are unrecognized. It is asserted that three per cent. of all persons born are without normal consciousness of right and wrong in their relations to others. They have retarded brain development. The part of the brain which constitutes the moral control or consciousness of the higher duties is wanting or undeveloped. Such persons are defectives, and insane in the general meaning of that word, and, like dements, are incapable of normal, healthy adjustment to the relations of life. When an apparently normal state of this brain function has existed and then a great abnormality follows in thought, word, and conduct, disease is present. Comparison of the conduct and character of inebriates, before alcohol is used and after they become habitués, brings out some startling facts that are unrecognized.

From the lowest type of a demented inebriate on one side to the moderate drinker at meals and the fashionable clubman, there is a distinct relation and chain of cause and effect. The clear moral insanity of the one is traceable to the other without any sharp dividing lines. The moderate drinker and clubman who proves to be the defaulter, or who is involved in conduct that is criminal, or who becomes a principal in crime, is suffering from disease differing only in degree from the degenerate inebriate tramp.

Moral insanity is a very prominent phase of all inebriety. Its absence in any given case is always an exception to the rule. A man with a high moral development after he becomes an inebriate may retain the form and externals of his previous character. He may be more emphatic in his display of some qualities, such as religion, truthfulness, and duty, and yet in other matters be oblivious of all obligation and duty. One such man who prayed for inebriates and lectured on temperance carried on an intrigue and sold his influence to the highest bidder. Another man acted as an agent for the sale of stolen goods, and at the same time carried on a great reform revival; and another was engaged in gold mine swindles, while lecturing every night for gospel temperance. The moral insanity was called hypocrisy, and, in legal phrase, was malicious, criminal, and vicious.

In reality it was degeneration and disease, the breaking down of one part of the brain while the others remained apparently clear. In our Civil War a noted general drank to excess at times. Previously he was noted for his hearty frankness and honesty, but was found unreliable, intriguing, and failed when needed most. He showed petty

weaknesses and untruthfulness, with malice that was unknown before in his character. He finally died a moral wreck, after the war was over, having become almost criminal in his thoughts and acts. A clergyman became a secret inebriate and later became involved in a low intrigue and was turned out of the pulpit. He was insane, his consciousness became palsied, and for a time he taught ethical truth automatically. The possibility of one part of the brain being affected and the rest doing normal work, and this condition being concealed, is a reality which experience confirms. The very close relation of one part of the brain with the other makes it impossible for health and disease to exist together, and yet moral insanity may be present and be concealed from general observation. A study of conduct will reveal it and a comparison with previous conduct will show its growth and development. The inebriate who has lost pride of character and sense of duty and obligation, truthfulness and honor, may seem to be the same in many ways for a long time, but sooner or later this moral diseased condition will spread and his whole organism show degeneration. The following are the notes of some cases which have occupied public attention and been the topic of some bitter discussion.

Case I.—John Blank. His father was a strolling actor of irregular character and an inebriate. He married a woman of average ability, from a good family. The father died before John was born, and two years later his mother married again. John was brought up with great care and tenderness. His later education was of the best character. He was a leader of his class as a scholar and an athlete. To his mother and intimates he displayed an intense selfishness, putting his interests and desires above all others, and had no consideration of the pain and distress of others. He was cruel in his conduct to anyone who was in his way to the achievement of any purpose or desire. He finally became a lawyer and was thoroughly unscrupulous in money matters, although not miserly or avaricious. As a politician he was without honor or pride of character, and would stoop to anything to accomplish his purpose. He married a rich woman and soon after swindled his father-in-law and possessed himself of a large property. Then he drank and began to live a fast life, had a mistress, attended horse races. Wherever he went he swindled and falsified and was feared by everyone who had any dealings with him. He went into stock gambling and was swindled and swindled others. To his wife and children he was cruel and violent in his conduct. After a period of excessive use of spirits, he killed his wife and made no effort to conceal it, or run away. On the trial his schemes for deception and fraud were revealed, to the astonishment of everyone. Truthfulness, honer, duty, and all the qualities which go to make character were absent. He was convicted, but the sentence was commuted to a life imprisonment. In this case moral idiocy was inherited.

The higher part of the brain was undeveloped and beyond the reach of culture and education. Without culture he would have early sunk to a low tramp criminal and burglar, and been a pauper degenerate, dying early. With culture he became a higher grade criminal, and yet he was unable to appreciate ethical truth or moral relations. He was insane from birth; alcohol intensified and developed this condition. The insanity was of the higher ethical brain, and concealed except to those who knew him intimately.

Case II.—The second case came from a good family and was normal in all his relations to others; was truthful, honest, and seemed generous and very kind. After a severe attack of typhoid fever, in which he was given large quantities of spirits, he began to use alcohol daily. His father died and left him in charge of a large business interest. His character changed. His regard for his word was lost. He was suspicious of his mother and brothers, and took money out of the business and concealed it. He left his home for a hotel, and, when drinking excessively, wrote violent scandalous letters to his family and employees. He associated with low women, but treated them harshly, refused to give them money, and was constantly in trouble. No public exposure disturbed him. He was frequently in court for petty swindles and refused to pay unless forced to. His business declined and was finally taken out of his hands, and he became a low blackmailer and beggar, drinking at all times and places. He was examined for lunacy and decided to be sane. No symptoms of insanity were found; nothing but wilfulness and vicious cunning, was the opinion of Philadelphia experts. Finally he was convicted as an accessory to murder and incendiarism, and sent to prison for life. This was clearly moral insanity acquired. His family and early history showed no trace of defective consciousness or moral weakness.

His parents were temperate, moral people, church members, above all suspicions. In his early life he attended church and Sunday-school, and was a lovable, attractive character. He began his business career with his father, and seemed in every way most honorable and honest. He displayed excellent judgment and was intrusted with large business interests which he faithfully executed. During his illness from typhoid fever his father died, and on his recovery he was put in charge of the business. A total change of character which followed his recovery might have been due to the spirits given, or the injury to some local center from the fever. At all events, the use of alcohol intensified and fixed this condition. In both of these a great deal of mental vigor and superficial sanity was associated with this low moral brain force. The experts could find no impairment of his reasoning and memory, and concluded his conduct was simply vicious.

The fact I wish to emphasize is that moral insanity follows the use of alcohol, and is present in all inebriates to a greater or less degree. This condition is inherited and acquired, and exists to a far greater extent than would be supposed. There are many excellent men who use spirits, not to a great excess, who are sufferers from the disease. The constant beer and spirit drinker will be found to present the most numerous examples.

VAGINAL SECTION IN RELATION TO PUERPERAL SEPSIS.*

By J. S. PRICE, M.D.,

BEAUMONT, TEXAS.

While in conversation with Dr. J. C. Taylor, first assistant to the late Dr. W. C. Pryor of New York city, he urged me to continue Dr. Pryor's method of treating puerperal sepsis, namely, by walling off the uterus from the neighboring lymphatics through a posterior section by a liberal packing of iodoform gauze. He emphasized and deplored the apparent want of appreciation shown by the indifference of

* Read before the meeting of the South Texas District Medical Society, Beaumont, Tex., December 13, 1905.

the profession at large to this life-saving, simple, surgical procedure.

Inasmuch as most of the local medical fraternity with whom the subject has been discussed have disregarded its importance, it seems pertinent to arouse a discussion of this method of treating puerperal sepsis by reciting my personal experience along with a word as to the author's rationale, hoping to excite renewed interest in a matter that should elicit our profoundest thought.

Dr. Pryor says: "In order to obtain a sterilization of the pelvic lymphatics through which the cocci have proceeded, the posterior *cul-de-sac* is opened by a broad incision and the intestines induced to leave the pelvis by lowering the patient's head. The pelvis is then filled with five per cent. iodoform gauze to the level of the tops of the broad ligaments, thus completely isolating the infected uterus. It is advisable to employ the gauze in snuggly folded strips, so as to facilitate its removal. In the disintegration of the iodoform, free iodine is liberated. This is rapidly absorbed, both by the inside of the uterus and by the peritoneum, and evidences of systemic saturation are manifested within a few hours, the iodine reaction being given in the urine and by the saliva. The intrauterine packings are removed and renewed in three days, to be finally removed in three days more. The *cul-de-sac* dressings are removed in a week, and each five days thereafter, until the *cul-de-sac* closes."

A classification of the infections into two groups, sapremic and streptococcic, should furnish a working basis founded upon the clinical conditions, not overlooking the fact that the two infections may be present at the same time.

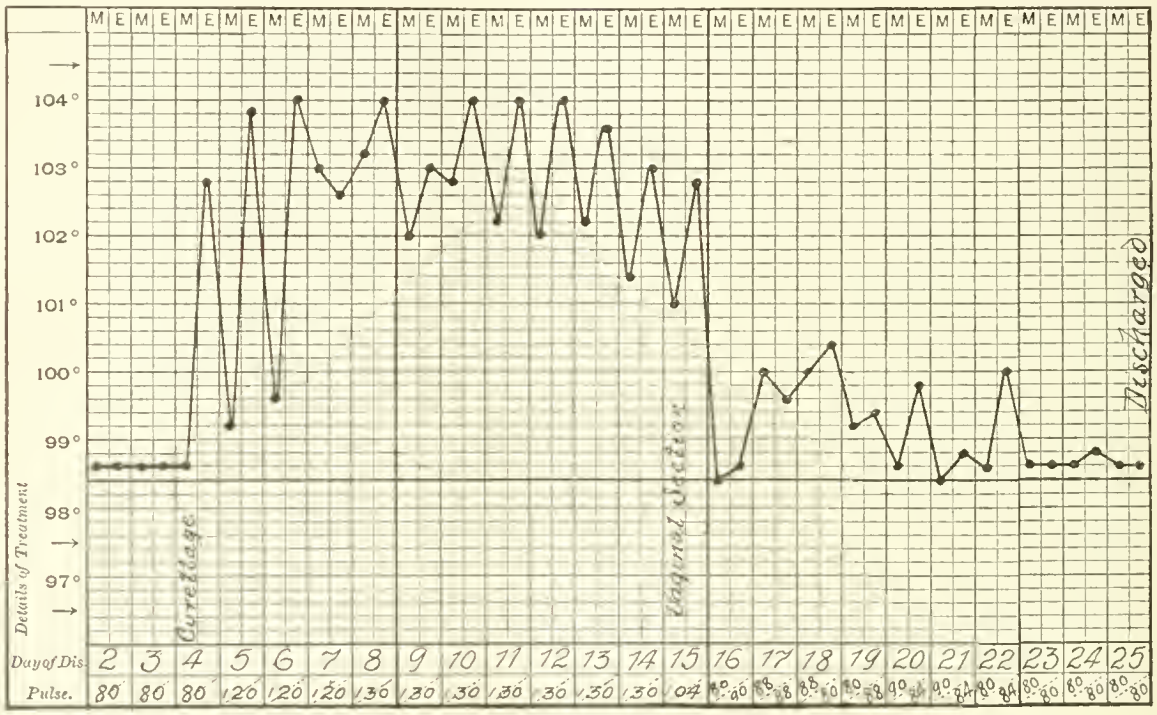
The streptococcic group comprises those cases in which we have a gradual onset, without chill usually; temperature, if ushered in by a chill, high at once, usually a gradual and continuous rise; pulse rapid from the first, more often at or above 120; discharge watery at first, odorless and purulent later.

General or localized peritonitis, with inflammatory exudates surrounding the uterine adnexa, is evidenced by early circumscribed pain and tumefaction.

When this array of symptoms is present the case is found to grow progressively worse, irrespective of our treatment directed to the uterine cavity, and it matters little whether we pronounce the infection sapremic or streptococcic, the pelvic lymphatics should be shut off from the focus of infection, for in so doing we lessen the chances of systemic infection and are given an opportunity to observe and correct any damage that may have already taken place locally; and finally, have the assurance of a more rapid and uneventful convalescence.

In making the above simple division of cases, it is not the intention in any way to disparage the benefit that might accrue from a culture test to confirm our suspicions of the gravity of the situation, but we, as country practitioners, being deprived of laboratory facilities, must rely on the teachings of observation and experience; and who of us has not had cases thus delineated go on from bad to worse in the face of our most approved ordinary measures!

Vaginal section is hardly worthy the dignity of being called an operation, as the veriest tyro in medicine should be able to perform it; the only point worthy of special mention is not to be stingy with the incision, it being important to be able to have abundant room for a liberal amount of gauze packing.



M E M E M E

the curette in cases of unquestionable streptococcic infection in the puerperium, recognizing that irreparable damage may thereby be done. This change of view is the outcome of the findings of the Commission of the American Gynecological Society in 1898, which showed that the normal mortality of puerperal sepsis was five per cent., whereas those cases in which curettage had been done and the streptococcus had been found gave a mortality of twenty-two per cent.

Be it understood that we do not deprecate the use of the curette when we have retained secundines to which the classical symptoms of sapremia, slow pulse, low temperature, etc., would at once call our attention, but there are yet those who do not distinguish between these cases, and go on doing harm by scraping and rescraping the uterine mucosa of every patient who shows a rise of temperature, thus losing sight of the fact that the infection is ofttimes beyond their reach, and the condition is demanding the operation in question as the only means of checking the onward march of the infection.

Before making our vaginal section, simple irrigation of the uterus with some mild antiseptic, preferably bichloride of mercury, then a liberal application of equal parts of iodine and carbolic acid, and finally a packing with iodoform gauze, completes the uterine toilet.

In conclusion, too much tribute cannot be paid to Pryor for his vaginal work, which stands as a monument to the man's genius, and he builded better than he knew when he conceived the idea of destroying pathogenic germs by the liberation of iodine in their presence in puerperal sepsis, for not alone is this accomplished, but the many inflammatory lesions that follow in the wake of this dread complication are cut short, if in their inception, and remedied if the condition has been for some time neglected.

Instead of these cases passing into the hands of the gynecologist after untold suffering, to be divested of their tubes and ovaries, the obstetrician, as he stands at the threshold of their troubles, will be their saviour.

The temperature chart, with notes of one case, is typically illustrative of what may be expected with almost absolute certainty after vaginal section in cases of this nature.

In the case, the temperature curve of which is here shown, there was hemorrhage for two days preceding abortion. On the morning of the fourth day the uterus was curetted and packed with iodoform gauze. This operation was followed by profuse sweating and a high temperature. On the eighth day the uterus was irrigated and iodoform in ether (10 per cent. strength) was instilled. On the eleventh day the uterus was swabbed with iodine and carbolic acid. The high temperature persisted, however, until the fifteenth day, when a vaginal section was followed by an immediate fall.

KORSAKOFF'S DISEASE: A REPORT OF FOUR CASES.

By EDWARD LIVINGSTON HUNT, M.D.,

NEW YORK

INSTRUCTOR IN NEUROLOGY, COLLEGE OF PHYSICIANS AND SURGEONS, COLUMBIA UNIVERSITY.

A REVIEW of the literature on Korsakoff's disease shows that the original article was published by Korsakoff in 1888. Many followed, at first in Russia, then in France and Germany, and finally throughout the civilized world.

It is now well established that the disease is a polyneuritic psychosis, which may, however, manifest itself without neuritic symptoms. The character of the psychosis is that of an amnesia. Jolly, in the *Charite Annalen*, very aptly summarizes the mental phenomena when he says: "The cardinal symptoms are (1) disturbances of memory and (2) pseudo-reminiscences." The etiology in the large majority of cases is alcoholic. Other conditions, however, may result in Korsakoff's disease and of these the most common are typhoid fever, pyemia, jaundice, and tuberculosis.

In all about 200 cases have been reported. This is my excuse for publishing the following four cases.

CASE I.—A. R. V., 61 years of age, married; heredity excellent; has always been healthy; is a brain worker and a high liver. Has never had any previous mental affection. Has mingled a great deal with men and has always been known as a regular and steady drinker, although never intoxicated. During the past six months he had been particularly busy, and as a result had worked particularly hard. About a month before I saw him he had met with a slight injury, which, however, gave him a great deal of pain and kept him awake at night. As a result he had been given sedatives and hypnotics. In spite of these he suffered a great deal and became very restless and intolerant. The opiates were increased and the alcohol decreased. He became more restless and intolerant; opiates were given freely and the alcohol further reduced. His condition grew worse. At the end of three weeks he began to make peculiar statements and soon after developed a delirium. It was about this time that I first saw him. He was anemic, emaciated, and very weak. The tongue was thickly coated. The temperature had been 100° for one day, but then was normal. The pulse was rapid and weak. There was a tremor of the facial muscles, of the tongue and of the hands. The knee-jerks were absent. There was no apparent pain in the calf muscles. The pupils reacted to both light and accommodation. The patient was very sick and drowsy. No diagnosis at that time was possible. All drugs except cardiac stimulants were withdrawn. The bowels were opened and the nourishment pushed. In forty-eight hours he was better, stronger, and more alert. Then the delirium showed itself. At first he simply muttered incoherently and picked at the bedclothes. Then as he grew stronger great motor restlessness developed. He was constantly tying and untying his dressing robe, continually going to the door, to the closet, looking in corners and under clothing for imaginary animals. The object of his search constantly changed, now it was a shoe, now a dog, now a pill. The slightest movement in the room changed the train of his thoughts. Nothing held the attention long. He grew stronger and the delirium increased. His words were incoherent, mixed sounds, and alliterative. He was completely disoriented as to time and place. Said it was summer, although it was winter, wished to go home, although he was at home. The familiar objects in his room were foreign to him. He did not recognize his wife. One minute he would speak to her and the next say he had not seen her in a month. He saw friends at the window, he spoke to imaginary friends in the room. He constantly heard the postman bringing mail.

His strength rapidly returned, he became violent, and then it was that the more characteristic symptoms appeared.

He became more coherent, that is, he used words, and no longer meanigless sounds. His memory, so far as recent events were concerned, was now absolutely gone. He could not recall what he had eaten a half hour before, whether or not he had eaten that day. He could not tell the hour of the day, the day, or the month, nor could he say whether he

had seen me before or not. He had hallucinations of sight and also of hearing. He constantly shifted from one subject to another. After a long sleep he would awaken refreshed, and at first coherent, only to ramble again. As he improved he became quite violent, resisted everything, and at one time thought his food was poisoned. Ten minutes later he would eat the same food while talking rapidly about thieves and squirrels. Eevery sound was misinterpreted, every word was transposed into some other meaning. He grew better and could be reasoned with. Then he would admit that his remarks were foolish. He began to read the papers and misconstrued what was in them. When reasoned with he laughed and admitted that he was wrong. He now became so much better that he could tell of events several years back, but whether or not he had slept last night was beyond him. His voice was still tremulous, and unconsciously he would use the wrong word. He realized that he had been sick. Things began to come back to him. He was no longer violent. He behaved himself and it was possible for him to go out. A month had passed and he was convalescing. Gradually but steadily this improvement continued. The tremor of the face and hands disappeared and the knee-jerks returned. The use of words became correct and the memory for recent events slowly returned. There was a steady general improvement manifest in both the physical and the mental symptoms. Occasionally he would forget something, occasionally ask the same question twice, but each week the occasion became more and more seldom. By the end of the second month he felt well enough to go away for a little trip, and very shortly afterwards was completely well.

Case II.—E. N. T., age 50, married; a man of leisure, who for ten years had been a hard drinker—one who at some time in every twenty-four hours had been intoxicated. The heredity was good, the previous history was good. The physical examination showed nothing. There was no tenderness of muscles and no loss of knee-jerks. Suddenly he became delirious. He was put to bed and for several days had a slight temperature, about 99-100 degrees. The pulse was weak and the patient was sick. At first the delirium was an incoherent muttering of inarticulate sounds—made even more so by the great tremor of the tongue and all the facial muscles, which was so bad that it was impossible to comprehend anything he said. His strength fluctuated for three days and then began rapidly to return. He became violent, abusive, and insisted upon using the telephone and going out. The disorientation of time and place was then complete. Although at home, he begged piteously to go home, looked out in his garden and said it was a certain street in a distant town. He recognized no one and miscalled the season of the year. He made loud outcries and called upon imaginary friends and foes. His language was profane and he became jealous of his wife, accusing her of infidelity. He was busy all the time, constantly opening doors and looking for things. He asked for the newspaper to see the stock market, and in the next breath asked where he slept last night. His memory for recent events was lacking, but as he improved he could recall events of his past life. He would tell me a long story about some terrible offense, which the servants had committed during my absence, the whole story being a fabrication.

This patient was in bed six weeks, and during that entire time he was quite sick. The first month the mental condition was one of complete confusion and incoherence; the physical condition was one of great weakness and cardiac failure. In the beginning it was difficult to get him to take any nourishment and constant resort was had to hypodermics. After a few days he consented to take liquid nourishment, and from then on began to gain. The physical improvement was steady and rapid. The mental condition remained one of incoherent confusion for fully a month. Towards the end of the fourth week the characteristic delirium developed. Then followed the great motor restlessness and the active objection to discipline and control. The mental improvement kept pace with the physical, and in another ten days the patient was quiet, tractable, but with a complete disorientation as to time and place; the memory for recent events was lost. The imagination had free rein.

The duration of this case from the first night of the delirium to the almost complete recovery, when he was able to be out, was about eight weeks. The recovery was steady and the patient did well. I was unable to follow him as long as I should have wished, but subsequently heard that he got well of this attack and later on returned to his drinking.

Case III.—Mrs. L. P., aged 35. This was a young woman, who had always led an irregular life, and who for several years past had been addicted to drinking. She had been in the habit of indulging in cocktails, wines, champagne, etc. The heredity was good. The previous history was good, as she had always been well up to eight months ago. At that time, without any apparent cause, she developed a condition of mental confusion and delirium. She was placed under restraint, but remained so only a short time. She then returned to her original mode of life and the mental condition became worse. I saw her only once, but on that occasion there were no symptoms of a neuritis, and, except a tremor of the face and hands, there were no physical signs. The general appearance was that of an alcoholic. The mental condition was very characteristic. The patient was much depressed and in great mental confusion. She was slow to take in the questions, and not at all certain of her replies. She used the wrong words and was quite disoriented as to time. In answer to the question as to what year it was, she replied 1907; and when the date in the newspaper was shown to her she laughed. A moment later she was talking of something else. She was very restless and kept constantly moving about. When in bed she moved her hands and feet, etc. Her memory for the events of the day was entirely gone. She could not remember who had visited her; said her husband had been in three times that day, when, in reality, he had not visited her once. She could not tell what she had eaten that day, and only after a great effort of thinking did she succeed in correctly naming the month. She denied having any hallucination of sight or hearing. The memory for events in her past life was quite good, and she could recall her former address. As to her present surroundings she was somewhat in doubt, and admitted frankly that her mental condition was one of great confusion.

Case IV.—A. B. C., 35, married; heredity good; previous history good. Had recently recovered from an attack of typhoid fever. Denied alcohol. The physical examination was negative except for great weakness in the legs. He came to the clinic because in the past two weeks he had found that he was unable to remember matters connected with his daily work and matters of very recent occurrence. Everything previous to his illness he could recall very accurately and very well, but in the daily routine of his work he found that his memory failed him; he found difficulty in recalling the exact date

and the month. Even if it was told him, he could not retain it.

This patient was very irregular in his attendance, and it was only at rare intervals that I saw him. The history of the typhoid was somewhat obscure, as it was impossible to ascertain as to whether the attack had been severe or mild, or, more important still, as to whether he had been given much or little alcohol. The main facts seemed to be that he had had an attack of typhoid, and that since then his memory had been poor. After several weeks he came in to report that he had completely recovered and was back at work.

To summarize these four cases then: The first was alcoholic plus drugs, the second and third were both uncomplicated alcoholic, the fourth was post-typhoidal, and may have been complicated with alcohol. Only one—the first—showed distinct neuritic symptoms, although both the second and fourth were weak on their legs, and probably in both the knee-jerk was diminished. All except the typhoid case showed a tremor. All four displayed characteristic and identical mental symptoms—loss of memory for recent events, disorientation as regards time and place, confusion followed by violence and motor restlessness.

Two out of the four patients recovered; none died; two returned to their excesses, and their cases may practically be considered as chronic.

71 East Fifty-second Street.

OPEN SAFETY-PIN SWALLOWED BY AN INFANT SIX WEEKS OLD, AND SUCCESSFULLY PASSED BY BOWEL SIX DAYS LATER.*

By B. VAN D. HEDGES, M.D.,
PLAINFIELD, N. J.
SURGEON TO MUHLENBERG HOSPITAL.

Through the courtesy of Dr. P. B. Cregar, the attending physician, with whom we saw the child in consultation, I have the privilege of reporting a case of an open safety-pin swallowed by an infant six weeks old, and successfully passed by bowel six days later.

The child was breast fed, of normal size and weight, and has always enjoyed good health. While the mother, with some open safety-pins in her hand, bent over the crib, the babe struck her hand with its little fist, dislodging one of the pins, which fell into its open mouth and was instantly swallowed. The child was immediately taken to the hospital for an *x*-ray examination. The pin could be most distinctly seen in the stomach, where it was being turned over and over by the peristaltic action. After further consultation it was decided not to interfere surgically, but to watch the case carefully and be prepared to do a laparotomy at the first indication of trouble.

For the next three days the only difference noted in the child's symptoms was that it slept better at night. There was no vomiting, no blood in the stools, no evidence whatever of any gastrointestinal irritation. On the fifth day the pin was seen in the descending colon, hinge end down, and the next day was successfully passed by rectum in a mass of semi-solid fecal matter. The pin measured 1 1-4 inches in length and 1-2 inch across at the open end.

In the *Journal of the American Medical Association* for November 25, 1905, Littig reports a similar case in an infant eleven months old. In 1903 Holt showed before this section a number of open safety-pins swallowed and successfully recovered from a child of eighteen months. As far as I know the case I have reported to-night is that of the youngest patient on record.

The question of immediate operation in this case, as against the let-alone policy, was hard to decide. One of the most eminent surgeons in the country advised gastrotomy without delay. On the other hand, Dr. L. Emmett Holt just as strongly urged keeping hands off until there was some indication of trouble.

From our experience in this present instance, and from the results of a rapidly increasing number of cases in children slightly older, who have all recovered without surgical interference, I am convinced that it is wiser to avoid the shock and dangers of an operation and to let nature take its course—especially when the child can be kept under constant *x*-ray observation.

*Read before the Pediatric Section of the New York Academy of Medicine December 14, 1905.

A Case of Multiform Tic, Including Automatic Speech and Purposive Movements.—Morton Prince has had a most interesting case of this kind under his care. The affection began twenty years ago, when the patient was fifteen years old. At first it was only a choreiform opening and closing of the eyelids of the usual type. Later the facial muscles became involved. This was followed by affection of the head, shoulders, arms, and legs. About five years ago the involuntary automatic speech developed gradually. Naturally the patient has a clean mind, is well-mannered, well spoken of, and keenly feels his affliction. The writer believes that this very fact is a factor in the psychosis. The affection is much worse when the patient is especially desirous of suppressing it, as in the presence of strangers and ladies. The automatic speech is interjected in the midst of nearly every sentence that is uttered. The patient does not know until the words are actually spoken what he will say. His writing is interrupted by spasmodic movements of the hand, which makes irregular scrawls on the paper. He declares that if he ever thinks of a peculiar movement he is apt to develop it. In other respects the patient is to all appearances a healthy and intelligent man. None of the stigmata of hysteria can be detected. A fear may originate a new tic with this patient. When he is alone he is never affected by automatic speech unless some one is within hearing distance. The tic movements, however, occur when he is alone. He exhibits automatic purposive movements of his hands when handling a knife or razor, but he never cuts himself. The essential feature of the automatic tics is that they are not absent-minded phenomena, but occur not only involuntarily, but while the patient is making every effort to control them.—*The Journal of Nervous and Mental Diseases.*

Cesarean Section.—Olshausen reports 118 cases of cesarean section of which 91 were for contracted pelvis. Of this number he himself performed 65 with three deaths, and his assistants 26 with six deaths. In describing the technique he advises the operator to make the abdominal incision very high. It should begin considerably above the umbilicus and terminate 8 or more cm. from the symphisis. In opening the uterus the incision is made across the fundus and down the anterior or posterior surface, according to the position of the placenta, which should be avoided. The dilatation of the superficial veins is usually a guide to the placental site. Twenty minutes before the operation, 0.12 gram of ergotin is given and no local measures are taken to prevent hemorrhage from the uterine incision. Compression of the cervix in any way is superfluous and undesirable, as it is apt to predispose to secondary hemorrhage. The suture employed is in two layers; the first takes only the muscular wall as deeply as possible, and the second is a continuous suture passing through the peritoneum and the upper layer of muscular tissue. Catgut is used as suture material.—*Zentralblatt für Gynäkologie.*

MEDICAL RECORD.

A Weekly Journal of Medicine and Surgery.

THOMAS L. STEDMAN, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 51 FIFTH AVENUE.

New York, March 10, 1906.

THE PHARMACOPEIA FETICH, AND OTHER THINGS.

A RECENT meeting of the Suffolk District (Mass.) Medical Society was devoted to a discussion of proprietary remedies and of the means best adapted to bring about a reform in the methods of their exploitation. The papers preceding the discussion, which were read by Drs. Frank Billings of Chicago and Frank G. Wheatley of North Abington, are published in the *Boston Medical and Surgical Journal* of March 1. Dr. Billings' paper was practically the same as the one read at Portland, Ore., last summer and recently published simultaneously in most of the State medical journals. It was devoted chiefly to ridicule of the uncouth names which manufacturers have seen fit to give to their preparations and of the "literature" in which they set forth the therapeutic virtues of these remedies. The absurdity of many of these names and of many of the claims of the manufacturers is patent, and nothing is easier than to make fun of them. As a remedy for the evil, the author urged the all-sufficiency of the Pharmacopeia to meet the therapeutic needs of the physician. "The Pharmacopeia," he said, "furnishes a list and description of chemicals and drugs, more than enough to meet the wants of the most ardent believer in drug therapy." Dr. Billings seems, however, to be a rather recent student of the good book, for he expresses sorrow that acetanilid—the *bête noir* of the Chicago wing of pharmaceutical reformers—"was made official in the last [not the last, but only the latest, we trust] Pharmacopeia," apparently unaware that it has been official for ten years. Dr. Wheatley's paper was in a measure a corrective of the one which preceded. The author put his finger on the cause of the "nostrum evil"—to adopt the term of the least judicious of the advocates of pharmaceutical reform—which is the therapeutic nihilism of Osler and others who are looked up to as guides in medical practice. It is only natural that young men who have been taught that no drug has any efficacy in the treatment of pneumonia and other so-called self-limited diseases, when confronted with a dying patient will grasp at any straw in the effort to save, and, finding only blank despair in the pages of their text-books, turn in their extremity to the rosy promises of cure in the literature of the makers of proprietary and patented remedies. This author also sends his hearers and readers to the Pharmacopeia as treating of "all the agents we need to use" though he also includes the Dispensatory, which fortunately treats of many non-official as well as of official remedies. In the discussion which followed the reading of these papers, Dr. White of Boston made the assertion that he had never in the fifty years of his practise, "prescribed a single remedy outside the lists of the Pharmacopeia of this or other countries."

The one ray of light in all this blackness of pharmacopeial conservatism was emitted by Dr. Morton Prince. He took occasion first to draw a sharp line of distinction between quack medicines exploited in the lay press and the secret pharmaceutical preparations advertised only to the medical profession—a distinction which is persistently ignored, to the detriment of pharmaceutical reform, by the *Journal of the American Medical Association* and its Council on Pharmacy and Chemistry. He deprecated justly the prescribing of secret remedies, and thought the medical journals might contribute to the reform by "a reasonable elimination of the most objectionable advertisements." But, "it is to be remembered," he said, "that if the journals advertise, the medical profession prescribes. This means that public opinion to-day is on the side of the manufacturers." The limits of an editorial article alone prevent us from reproducing entire the remarks of Dr. Prince as reported in our Boston contemporary. He has shown, as no other contributor to this vexed question has succeeded in doing, the true way of pharmaceutical reform. If medical men will refuse to prescribe remedies the composition of which is unknown, the "nostrum evil" will be at an end. But the physicians of this country are, as we have said before, not babies to be guided by a certain coterie of pharmacologists and therapeutic nihilists—a queer combination—whose slogan is, Back to the Pharmacopeia! and who seem to think the way to reform the manufacturers of proprietary remedies is to class them with the makers of quack medicines. The sentiment expressed in the couplet, "It is a sin to steal a pin," has made many a professional thief, and the same principle adopted by the intemperate organ of the American Medical Association and its State satellites will assuredly drive some of the weaker and less honorable manufacturing chemists into the ranks of the avowed "patent medicine" men.

The attempt to coerce practitioners of medicine to a strict adherence to the drugs official in the Pharmacopeia is less wicked, but more foolish. How many physicians can echo Dr. White's assertion that he has never prescribed any but pharmacopeial remedies? We hope, for the sake of their patients, that they are few in number. The latest revision of the U. S. Pharmacopeia has admitted a number of remedies of undoubted worth. Why were these admitted? Simply because the medical men of the country had been using them, though unofficial, and had found them indispensable in their practise. If they had confined themselves, as Dr. Billings would have had them, to the remedies declared official by the seventh revision of the Pharmacopeia, these new drugs would still be "secret nostrums" and among the *noli me tangere* of the unco guid. A physician high up in the councils of the American Medical Association recently sent a letter to the organ of the Association in which he exposed the absurdity of the contention that "ethical" practitioners should confine themselves to pharmacopeial drugs, and the editor of the organ answered that he had set up a man of straw. But Dr. Billings, the treasurer, we believe, of the Association, and an ex-

president, refutes the contention of the editor-secretary, and swears by the Pharmacopeia as the guide of practise for all ethical prescribers.

The Medical Record is heartily in favor of pharmaceutical reform, but it despairs of any progress so long as the cause is in the hands of the foolish and discordant Chicago missionaries. A little common sense and a little restraint in the use of invective would go a long way to bring about a reform which now seems impossible.

TAX-FREE ALCOHOL.

Numerous attempts have already been made by enlightened statesmen to secure for this country the manifest and manifold advantages that would accrue to countless industries were the ill-advised revenue tax of something over two dollars a gallon, now imposed on grain alcohol, removed. Each well-meant effort has, however, been rendered ineffectual either through the illogical and often fanatical opposition engendered by self-interest or a mistaken sense of duty, or through the perhaps still more exasperating passive resistance offered by the tergiversations of the divers Circumlocution Offices whose function it is to prepare the way for legislative consideration, but whose delays and vacillation cause many worthy measures to die a natural death of old age before final action can be taken. For some weeks the Committee of Ways and Means has again been considering the question, the subject of its deliberations being a bill sponsored by Representative Hill of Connecticut, and having for its object the placing of ethyl alcohol on an industrial parity with methyl alcohol and gasoline. The enormous handicap upon American manufactures in competing with European products coming from countries such as Germany, where the use of ethyl alcohol is exempt from the restrictions existing in this country, is a matter of common knowledge, and need not be discussed at this moment, nor is it necessary to point out how advantageous to the farmer it would be were he allowed to ship a portion of his grain in the compact form of alcohol, which would also serve as fuel for his agricultural machinery. It is stated that the greatly increased consumption of gasoline and its congeners, owing to the constantly growing prevalence of motor machinery of all sorts, must soon be followed by a relative insufficiency in the supply of those commodities, which will entail a rise in price, whereas tax-free alcohol is well adapted to subserve the same purposes with little or no alteration in the motors, and an appreciable pecuniary advantage.

Leaving aside all of the purely commercial aspects of the question, recent experiences have demonstrated the danger both to eyesight and to life attending the employment of wood alcohol in the arts and industries, and it is equally well-known to how great an extent the same agent is employed in the adulteration of cheap beverages, flavoring extracts, preparations of Jamaica ginger: it is even used, according to the Health Commissioner of New York, in the manufacture of communion wine. Given an untaxed grain alcohol, the temptation to resort to sophistications of this sort would cease to exist and the health and earning power of the artisans in many branches of industry would no longer be jeopardized. The loss of revenue to the government involved if such a measure were to be enacted is one that the ingenuity of legislators could easily compensate in other ways, while the moral and economic turpitude of a tax that assails not only the country's industries but also the physical welfare of its inhabitants, is sufficiently apparent to render all considerations of revenue production entirely beside the mark. The objections of the total abstinence advocates may be met with equal positiveness, for ethyl alcohol may, without detriment to its technical applications, be "denaturized" in such a way as to render its use as a beverage impossible to any but those casehardened topers who even now take kindly to wood alcohol itself and the matter of illicit redistillation would be no more difficult to deal with than is the work of the "moonshiners" at present.

While institutions of learning are already allowed tax-free alcohol for their laboratory purposes, the benefits of cheaper—even though "denaturized"—alcohol to the medical profession, both in research work and in practise, would be very great in numerous ways that it is hardly necessary to suggest, and it is highly desirable that physicians should use their influence in support of a measure which will mean so much for the material and hygienic welfare of the country.

The Transmission of Syphilis to the Third Generation.

It has often been claimed that syphilis cannot be transmitted beyond the second generation, but proofs have been accumulating which seem to demonstrate that such a restriction does not in reality exist. Competent authorities are now agreed that degenerative or dystrophic effects may be transmitted to the third generation, although the idea that the disease may likewise be transmitted in its active or virulent state has not been universally accepted. C. F. Marshall, writing in *Treatment* for December, 1905, calls attention to the recent advances in the study of this subject, particularly by Fournier and Tarnowsky. In a series of over one hundred cases collected by the former, only a small proportion of the descendants were found to be free from syphilitic stigmata. Many of these were seen to be of such a character, however, that they could be accepted as evidence of ancestral syphilis only by enthusiastic followers of these doctrines. Admitting the possibilities of the transmission of the degenerative effects of syphilis to the third generation, that of the virulent type is more difficult of proof, although a number of apparently undoubted cases are now on record. Time and treatment are the two most important factors in the process. It is well known that the signs of hereditary syphilis may be delayed until the procreative age, and in this way an individual afflicted with hereditary syphilis might transmit the disease in a virulent form to the offspring. That this does not happen more commonly may be ascribed to the fact that marriage is not apt to take place with the subject in the condition noted, and at this time the disease is usually attenuated by time, and also by treatment if this has been used. The two chief obstacles to actual proof of transmission to the third generation are the possible reinfection of the second generation and the intervention of another syphilitic genitor. The latter factor always constitutes a stumbling block, for, although we can have no doubt of the relationship between any given child and its mother, it

must be acknowledged that we have no means of proving paternal parentage by scientific methods.

Vascular Spasm and Fibrosis.

There is a certain symptom complex associated with the onset of old age which we have learned to ascribe to definite and well-marked changes in the kidneys, the heart, and the blood-vessels. It is often difficult to determine which of these constitutes the primary lesion, for when the patient comes under observation all three are likely to be affected. There is one group of these cases in which the vascular symptoms predominate to such an extent that the disease may be assumed to reside primarily in the vessels rather than in the kidneys. In a recent communication, H. A. Hare (*Therapeutic Gazette*, December, 1905) describes this class as characterized mainly by high arterial tension, without any renal lesions demonstrable by the ordinary symptoms or by uranalysis. Hare distinguishes three types of high tension; in the first, the tension persists as the result of a spasm due to prolonged nervous stress combined with certain abuses as to habits of life, food, and drink. In the second, there is, in addition to the spasm, a gradually developing fibroid change in the vessels. The third includes cases in which after a prolonged period of high tension, there develops more or less suddenly a persistent low tension, in which the arteries are relaxed and distended to such a degree that they resemble veins. In accordance with these clinical distinctions, the histories are given of a number of cases which show an astonishingly high arterial tension not affected very much by the usual remedies. The heart seems to have escaped here sufficiently to maintain the tension. As Hare points out, however, it is quite possible for the muscles of the larger vessels to undergo hypertrophy, as fibrosis in the peripheral vessels increases, in a manner similar to that which takes place in the heart. And likewise it is equally probable that vascular compensatory hypertrophy may give way just as the cardiac variety does. This rupture of compensation is looked upon by Hare as a fortunate circumstance, for it often gives the heart a rest and allows it to recover from its fatigue, and life in this way may be saved. It is also possible for the affected vessels to recover their power if the peripheral fibrosis is arrested, but cardiac stimulants in these cases are not indicated as much as rest and the proper employment of alteratives and vascular sedatives. It is evident, moreover, that in cases in which the high tension is due to fibrosis the nitrites are of little value compared with the iodides. A knowledge of the points here noted will, in cases similar to those described, lead to the giving of a better prognosis than would otherwise be indicated, and to the institution of a different mode of treatment from that usually employed.

The Smoke Nuisance.

At the meeting of the New York Academy of Medicine—a body which under the present public-spirited and intelligent administration is well fulfilling its mission as the guardian of the people's health—held March 1, resolutions were passed reminding the Health Department of its duty in the enforcement of the law against pollution of the atmosphere by coal smoke. It is full time something was done to abate this evil unless we are content to sacrifice the beauty of our Italian sky to the greed of wealthy corporations. The records show that there has been a progressive decrease during the past few years in the number of complaints by Health Department inspectors, yet it is apparent to even the casual observer that the number of offenders against the smoke law is steadily increasing. Electric light is a great convenience, and even a necessity, but we need not barter our glorious sunlight to obtain it. There are some nuisances entailed by modern progress which must be endured, but for the smoke nuisance there is no excuse. Bituminous coal can be burned without this wilful waste of carbon, and it is strange that those in charge of power-houses and other large consumers of soft coal should not see that the prevention of smoke by suitable devices, or even by more careful stoking, would effect a very appreciable economy in fuel. They should be made to see it. One by one the great cities of the East are being devoured by the black smoke beast—even tidy Philadelphia is becoming grimy and soot-soiled—and if New York is to be saved, speedy and energetic action must be taken by the Health Commissioner. We have gone back to dirty streets, but let us at least keep the air clean.

News of the Week.

English as She Is Wrote.—The following is one of the articles of the proposed Constitution of the new Association of State Medical Journals: "6. Expulsion: Any member of this Association which shall publish an advertisement of any remedy which is disapproved by the Council of Pharmacy and Chemistry of the American Medical Association for twelve months after due notice of such disapproval shall have been mailed to the last known address of the persons duly qualified as representatives of such member, shall be dropped from this Association; and shall not be eligible to reelection to membership until it shall have complied with the requirements of the Council's rules for a period to be determined by subsequent ruling, but not less than one year." We would suggest that the Council on Pharmacy and Chemistry analyze this and publish its ingredients, for in its present form it is a secret article and therefore unethical.

A Health Commissioner for Brooklyn.—A bill has been introduced into the Assembly by E. C. Dowling, and one into the Senate by Charles Cooper, having the object to create the office of Health Commissioner for the Boroughs of Brooklyn and Queens, and thus take from Commissioner Darlington control of the affairs of the Health Department in those two boroughs. At present Brooklyn is represented by an assistant sanitary superintendent, and the physicians of the two boroughs believe that the Health Department of that part of the city cannot be administered with satisfaction to either the medical profession or the public because of lack of authority and direct responsibility. The bills have the endorsement of Dr. Campbell, President of the Medical Society of the County of Kings, and of Bird S. Coler, President of the Borough of Brooklyn.

A Medical Papyrus.—Advance copies of a work, the first of a series of publications on Egyptian archeology, have been received from Leipzig by the University of California, at Berkeley. It is the work of Dr. Geo. A. Reisner, Hearst lecturer on Egyptology in the University. The series is dedicated to Mrs. Phoebe A. Hearst, who, in the interests of this institution, bore the expense of expeditions to Egypt, Peru, and other countries, occupying five years. The volume contains the text of the medical prescriptions and incantations contained in the original papyrus, which was brought to the

camp of the Hearst Egyptian expedition in 1901 by a peasant. The papyrus belongs to a period between the twelfth and eighteenth Egyptian dynasties. Medical knowledge at that time, judging from the character of the compilation, consisted of a great number of small collections of prescriptions by different physicians, preserved at different towns or in different temples. The prescriptions in this are less systematically arranged than those of the Ebers papyrus.

The American Laryngological, Rhinological, and Otological Society.—The twelfth annual meeting of this society will be held under the presidency of Dr. Jas. E. Logan of Kansas City, Mo., on Monday, Tuesday and Wednesday, June 11, 12, and 13, 1906. Prizes have been offered by the following members of the society: J. E. Sheppard, M.D.: Topic, "The Best Classification of Non-Suppurative Affections of the Middle Ear," the same to be based as far as possible on pathological research; prize, $100. D. Braden Kyle, M.D.: Topic, "Atrophic Rhinitis." Prize, $100. Charles W. Richardson, M.D.: Topic, "What Operative Treatment Offers the Best Results for the Cure of Chronic Suppurative Frontal Sinusitis;" prize, $100. Norval H. Pierce, M.D.: Topic, "Original Work on Rarification of the Labyrinthine Capsule;" prize, $100. Edward B. Dench, M.D.: Topic, "Chronic Non-Suppurative Inflammation of the Middle Ear;" prize, $100. The above-named prizes may be competed for by members of the society only, and competitors are requested to present their papers to the Secretary before April 15, 1906. The successful paper for each prize will be read at the annual meeting. Competitors are requested not to sign papers, but to inclose name in a sealed envelope. The Council further announces that the society holds for the encouragement of research a fund of $500, the whole or a portion of which may be awarded at the discretion of the Council, to any of the society's members presenting an essay embodying original work in subjects pertaining to laryngology, rhinology, or otology. The Council reserves the right to make no award, if in its opinion the essays are of insufficient merit. All essays submitted must be anonymous, being designated by a motto or device, the writer's name and address accompanying the essay in a sealed envelope inscribed with the same device or motto as the essay. The Secretary is Dr. Wendell C. Phillips, 40 West Forty-seventh street, New York City.

Separation of College and Hospital.—At a recent meeting of the Board of Directors, action was taken separating the management of the Angelus Hospital from that of the College of Physicians and Surgeons of Los Angeles, Cal. Dr. C. W. Bryson was elected Dean of the college, and Dr. Chas. B. Nichols President of the Board of Directors of the hospital. Dr. James P. Booth was elected to succeed Dr. Nichols as editor of the Los Angeles *Medical Journal,* published by the college.

Formaldehyde Disinfection.—The Illinois State Board of Health has been conducting a series of experiments in its laboratory in formaldehyde disinfection, and as a result the board now feels justified in recommending formaldehyde for use in disinfection after contagious diseases, if employed with potassium permanganate, and with 40 per cent. aqueous solution of formaldehyde. It believes that in properly sealed rooms positive and reliable disinfection can be secured by the use of three and one-half ounces of potassium permanganate and one pint of formaldehyde solution to each 1,000 cubic feet of air space.

Seaside Hospital for Tuberculous Children.—John D. Rockefeller has offered to give the Association for the Improvement of the Condition of the Poor $125,000 toward the erection of a permanent seaside hospital for children suffering from tuberculosis of the bones and glands, on condition that a like amount is raised before July 1 and that the permanent maintenance of the hospital is assured. Various donors have already pledged themselves to contribute sums amounting to $42,000. It is said that the interest in the project is to a great extent due to the prominence into which the Sea Breeze Hospital at Coney Island was brought by President Roosevelt's visit last summer.

Decision Against a Board of Examiners.—The Board of Medical Examiners of the State of California revoked the license of a woman physician of Los Angeles on the ground of alleged unprofessional conduct. The case was taken to court, and recently the Supreme Court has handed down a decision in favor of the doctor, restoring her right to practise. The decision further contains the statement that the statute of 1901 is "vague, indefinite, and uncertain."

San Francisco Polyclinic Banquet.—The sixteenth anniversary of the Polyclinic was celebrated on February 16 with a banquet at the Union League Club, Dr. Leo Newmark serving as toastmaster. After a most enjoyable evening, the following officers were elected for the ensuing year: *President,* Dr. Chas. G. Levison; *First Vice-President,* Dr. Henry L. Wagner; *Second Vice-President,* Dr. Geo. W. Merritt; *Treasurer,* Dr. Louis Bazet; *Secretary,* Dr. Martin Regensburger. Among the other physicians present were Drs. Wilson, Shiels, Langley, Porter, Zobel, Evans, Bruns, Carpenter, and Ryfkogel.

Harvey Society Lectures.—The twelfth lecture in the Harvey Society course will be delivered by Professor Theobald Smith of the Harvard Medical School, at the New York Academy of Medicine on Saturday, March 10, at 8:30 P.M. Subject, "The Parasiticism of the Tubercle Bacillus and Its Bearing on Infection and Immunity." All interested are invited to attend.

The San Diego County (Cal.) Medical Society has reelected the officers of the preceding year to serve during 1906, Dr. J. M. French, President, and Dr. T. L. Magee, Secretary and Treasurer.

The Training of Nurses.—On March 29 a symposium on the training of nurses will be held at the New York Academy of Medicine, to discuss the question of the overtraining of nurses and to suggest remedies.

The Lisbon Congress.—Sir Patrick Manson will not deliver his proposed address at the International Medical Congress, and Prof. Waldeyer will take v. Bergmann's place as Germany's official representative. As already noted in the MEDICAL RECORD, America will be represented by Dr. N. Senn of Chicago.

The New York Society for the Relief of the Ruptured and Crippled reports that in 1905 963 patients, mostly children, where treated in its hospital at Forty-second street and Lexington avenue, and that 44,157 treatments were given outside. The committee which makes this report states that the hospital needs funds. Every year it runs $40,000 behind its permanent subscriptions and endowments.

The New York Orthopedic Dispensary and Hospital.—During the year just ended 4,220 patients were treated in the dispensary and hospital, and 3,431

visits have been made by the hospital staff to the homes of patients. This year the expenses will be considerably increased. Owing to the entirely inadequate accommodations for the nurses, it has been found necessary to add to the hospital property a small building on Fifty-eighth street, which will be used as a nurses' home, and to relieve the congested consulting rooms.

Hazed Medical Student Sues.—A student at the Creighton Medical College, Omaha, is about to sue the faculty for $50,000, on the ground that as the result of hazing he has been completely incapacitated. He states that he was dragged from his classroom by sophomores, who intended to throw him into a ventilating shaft. He fought, and was kicked in the back, his spine being injured, and he has had to use crutches ever since.

Dr. J. B. Mickle, superintendent of the Metropolitan Hospital on Blackwell's Island, has handed in his resignation, to take effect on March 31. Ill health is the cause.

St. Francis Hospital Dedicated.—The new St. Francis Hospital, occupying the entire block bounded by One Hundred and Forty-second and One Hundred and Forty-third Streets, Brook and St. Anne's Avenues, and containing 400 beds, was dedicated last week by Archbishop Farley.

Metropolitan Hospital and Dispensary.—At the annual meeting of the Metropolitan Hospital and Dispensary, held on March 1 at the old hospital building, 248 East Eighty-second Street, it was announced that ten donors had given $500 each toward a new hospital building. The Building Committee was authorized to sell the present hospital site at the proper time, and immediately to purchase the new building site already selected.

The Bushwick and East Brooklyn Dispensary at Myrtle and Lewis Avenues has received a gift of $10,000 from Peter Wyckoff of Williamsburg, who has presented a similar amount to each of several other charitable institutions.

Record Fasting.—Sacco, the Hungarian fasting expert, has completed a test fast of forty-five days under observation in London, and claims the record. During this period he smoked 952 cigarettes and drank twenty-two bottles of table water. At the conclusion of the test he had lost fifty-five pounds. His respiration was 23 and pulse rate 84, and he is reported to have been in satisfactory physical condition.

Centenarian Diversions.—At a marriage recently solemnized in a Kentucky town, the bridegroom was 101 and the bride 100 years of age. Their courtship is said to have been an "intermittent" one of seventy years' duration. On March 3 a court in Washington, D. C., found a man alleged to be 108 years of age, guilty of habitual drunkenness.

The Widener Home for Crippled Children at York Road and Olney Avenue, Philadelphia, erected at a cost of $2,000,000 by P. A. B. Widener as a memorial to his wife, was opened on March 3. The institution comprises a set of magnificent buildings and a park of thirty-five acres, consisting of woodland, lake, and gardens. Dr. DeForest Willard, surgeon-in-chief of the institution, in his opening address announced that Mr. Widener had set aside a further sum of $3,000,000 as an endowment fund for purposes of maintenance.

Benzoic and Salicylic Acids in Foods.—Dr. Wiley, chief chemist of the Department of Agriculture, on February 26 presented before the House Committee on Interstate and Foreign Commerce some of the results of his experiments upon his "poison squad" with salicylic acid as a food preservative. Although deleterious to health, he declared that salicylic acid is less harmful than benzoic acid, boracic acid, or any of the other preservatives. He asserted that benzoic acid unquestionably is injurious to health if taken into the system regularly. He thought that the occasional use of such foods as contain benzoic acid, although harmful, might not be noticeable. Cranberries, he said, contain enough benzoic acid to make them undesirable as an article of daily diet.

Street Noises.—Fifty women, representing the West End Women's Republican Association, appeared before the Aldermen's Committee on Public Health March 1 to protest against street noises. Their efforts were especially directed toward getting the board to pass an ordinance restricting hucksters, scissors grinders, etc., to certain streets.

Leprosy Hospital in the Hawaiian Islands.—Dr. Walter R. Brinckerhoff of the Harvard Medical School has received the appointment as director of the United States government leprosy research hospital which is to be established on Molokai, the island on which the lepers are now segregated.

Obituary Notes.—Dr. Joseph Edgar Wells of Brooklyn died on February 27, in his forty-first year. He was a graduate of Jefferson Medical College and had practised in Brooklyn for eighteen years.

Dr. William A. Drake of New York City died on March 1, at the age of thirty-nine years. He was graduated from New York University Medical College in 1889.

Dr. Samuel D. Brooks of Springfield, Mass., died on February 27, of angina pectoris, a few days before the completion of his ninetieth year. He received his medical diploma from the Pittsfield Medical College in 1841, and then went to Norwich, where he practised until 1848. In 1853 he was made superintendent of the State Almshouse at Monson, and in 1858 he was appointed superintendent of the New York Juvenile Asylum. He held this post until 1871, and during this time instituted many reforms in the institutional care of children. He then returned to Pittsfield and engaged in general practise, which he continued until about fifteen years ago. Dr. Brooks was a true son of the Revolution, as his father fought in that war.

Dr. J. E. Bingham of Walla Walla, Wash., died on February 19 of Bright's disease, at the age of sixty-one years. Dr. Bingham was born in Williamsport, Penn., and was graduated from the Jefferson Medical College in 1868. In 1870 he went to the Pacific coast and served for a time as acting assistant surgeon in the United States Army, and he later was a member of the State Board of Medical Examiners.

Dr. Joseph Hils of Woonsocket, R. I., died on February 23, in his fifty-seventh year. Dr. Hils was born in Canada and received his medical degree from McGill University in 1873, since which time he had practised continuously in Woonsocket. He was a consulting surgeon at St. Joseph's Hospital, Providence, and a member of the Woonsocket Hospital staff since its foundation in 1888.

Dr. John C. Spray of Chicago, Ill., died on February 20, at the age of sixty-one years. He was graduated from the Medical School of Northwestern University in 1869, and was superintendent of the Dunning Institutions from 1878 to 1889. He was well known as an alienist, and was frequently called as an expert in legal cases in which questions of insanity were involved.

Dr. William H. Hinton of Ogden, Utah, died on February 19, of meningitis, at the age of thirty-seven years. Dr. Hinton was born in Missouri, and received his medical education at the Rush Medical College. He served as railroad surgeon on several lines until two years ago, when he commenced practise in Ogden.

Dr. Thomas N. Birnie of Springfield, Mass., died of Bright's disease in Orlando, Fla., on February 26, at the age of fifty-one years. Dr. Birnie was graduated from Yale University in 1876 and from the College of Physicians and Surgeons in New York four years later. For the last fifteen years his health had been very poor.

Dr. F. Griffin of Mapleton, Ia., died on February 6, at the age of fifty-nine years. He was born in Boston, Mass., and in 1864 enlisted in the army and served through the Civil War, at the close of which he began the study of medicine, and was graduated from Rush Medical College in 1869. He practised in Wheatland until 1878, when he removed to Mapleton and had practised there ever since.

Dr. C. D. Osburn of Sherwood, Ore., died on February 19 of heart disease. He was a graduate of Jefferson Medical College in the class of 1886.

Dr. Robert C. Hutchinson, surgeon of the S. S. *St. Louis* of the American Line, died of pneumonia on February 27 and was buried at sea. He was forty-nine years old and was graduated from the Medical Department of the University of Pennsylvania twenty-five years ago. He practised in Trenton, N. J., until eight years ago, when he took up a sea life for health reasons.

OUR LONDON LETTER.

(From Our Special Correspondent.)

DR. CHALMERS ON INFANTILE MORTALITY—CANCER OF THE STOMACH—PREVENTION OF PHTHISIS—HOSPITAL LETTERS—ALCOHOL AND IRRESPONSIBILITY.

London, February 16, 1906.

Dr. A. K. Chalmers, Medical Officer of Health for Glasgow, has been investigating the history of infantile mortality by means of statistics which he has collected, extending over the last half century. He read a paper on the subject last week in London. From the tables he presented it appeared that the mortality increased largely at the early part of that period, then met a check and recently revived. The causes were diverse; some were hereditary, and therefore outside the influences of administrative supervision. The contrasts shown by the figures were great, the mortality being higher in some of the smaller Scottish towns than in populous centers. A very instructive table showed the infantile mortality in Glasgow during two years of each decade from 1870 to 1902. Earlier figures were not reliable, and doubt as to the correctness of some later returns may be felt, especially as to such diseases as those returned as digestive, nervous, and tuberculous. A large number were ascribed to immaturity. Dr. Chalmers thought artificial feeding chiefly due to poverty, and suggested that not a few doctors did not understand the conditions applicable to the feeding of infants. As to the use of sterilized milk, he said doctors were divided on the problem, or as it might be called, the conundrum.

The surgical treatment of cancer of the stomach was the subject of a paper at the Clinical Society by Mr. Moynihan. It was based on 50 operations, viz., 35 of gastroenterostomy with 5 deaths; 10 of gastrectomy, 3 deaths; 5 of gastrotomy, no death; 3 of jejunostomy, no death, 6 of exploratory laparotomy, 1 death. He considered gastroenterostomy indicated when an irremovable growth caused pyloric obstruction, but when there was no such hindrance at the outlet the relief was not commensurate with the risks. In suitable cases it prolonged life and let the last weeks be passed in tolerable comfort. As to gastrectomy, improvements in technique permitted a wider range of cases than formerly, not only for cure but even as a palliative. In the five cases of gastrostomy the growth caused obstruction at the cardiac end. Jejunostomy, he said, was adapted for cases in which gastroenterostomy is impossible, by reason of extensive involvement of the stomach and gastrectomy, contraindicated by secondary deposits. It may prolong life for a brief period, sometimes very important. As to exploratory operations to confirm diagnosis, Mr. Moynihan declared they were not, as some fancied, devoid of risks. When close scrutiny and handling of parts is necessary for diagnosis they may be done, but when the insertion of a finger suffices the clinical diagnosis needs no corroboration. The frequent evidence of cancer at the pylorus and the regular invasion of the curvatures were facts well brought out in his series. He believed a diagnosis between pyloric and prepyloric cancer was often possible by careful attention to the onward march of symptoms. A previous history of gastric ulcer had been noted in twenty-four out of thirty-nine cases examined on this point. He observed that both ulcer and cancer affect the same portion of the stomach wall, and thought chronic inflammation might be a precursor here as in other parts of the body. The insidious nature of the disease rendered early diagnosis difficult, but he hoped more careful application of clinical methods would lead to earlier recognition, and that the surgeon would be more often called to *make* a diagnosis rather than to *confirm* one arrived at by waiting until too late.

Mr. Mayo Robson, who had operated on 120 cases, also urged the importance of early diagnosis. He was rather in favor of exploratory laparotomy, and thought the risk not great if done early enough. He would advise it when medical treatment was of no avail in a few weeks.

In reply to questions by other speakers Mr. Moynihan said he always removed the growth straight away whenever possible, without a preliminary gastroenterostomy, unless the patient was very weak. In over 50 per cent. of his cases ulcer had been diagnosed years before cancer developed. In his opinion chronic dyspepsia was generally due to ulcer, vomiting being rare and hematemesis more rare still. Hospital records he considered unreliable unless the point had been specially looked for. He never did enteroanastomosis, as in his operation it was impossible, as the upper end of the opening was more than an inch below the duodenojejunal flexure. He used clamps, as they saved time. He removed all glands, whether obviously cancerous or not.

The association for the prevention of consumption is issuing a memorial to every public authority, directly or indirectly reponsible for the public health, urging them to exercise all powers vested in them for checking preventable disease. It is pointed out that the chief problem is the destruction of expectoration, and to secure that all phthisical patients, at every stage, should be under supervision and instructed as to the danger to themselves and others arising from the sputum. They should be surrounded by proper precautions, or, if necessary, removed and isolated. But such a task is beyond the power of any single authority, and requires the cooperation of all medical officers and municipal authorities. Voluntary notification has been tried in eighteen out of the twenty-nine London boroughs, and in Manchester, Liverpool, Brighton, and other towns, and has been, it is declared, very successful. It is compulsory in Sheffield, but this may be thought an extreme measure by some, and so it is suggested that it need only be obligatory on Poor Law doctors, and perhaps in hospitals and dispensaries. Recommendations for the domestic isolation of advanced cases and for institutional isolation are made, and it is said in them municipal forethought and energy would find an opportunity of effectually controlling dissemination of consumption. For early cases, sanatoriums might be provided, but these require time and money. Meanwhile, effective supervision of advanced cases is urged.

Tuberculosis follows in the train of poverty. Better housing, food and other improvements of the lot of the poor are advocated, but the complete attainment of all needs means the abolition of poverty and a revolution in the habits, character, and inclinations of the poorest classes. Improvidence, self-indulgence, want of cleanliness, and so on, all tend to poverty and disease. But though poverty, vice, and shiftlessness cause consumption, that disease in turn causes poverty. Out of 4,000 consumptive paupers under Dr. N. Raw of Liverpool, 60 per cent. became poor because they were phthisical. The national association urges that protection against consumption is as much a duty of sanitary authorities as against typhoid fever, and every precaution taken is also antagonistic to all infectious diseases, and conduces to the health and vigor of the community.

The Charity Organization Society has a special meeting on Monday to consider the question of Hospital Subscribers' Letters of Recommendation. Mr. Nelson Hardy read a paper on the subject in which he maintained that the system was condemned by all medical authorities. In 1896 the Hospital Reform Association recommended

its abolition, and since then the British Medical Association has passed a resolution in the same sense. The Sunday and Saturday Funds receive a proportion of letters. On the other hand, King Edward's Fund requires no such return from participating institutions. Inability to pay for adequate treatment should be the only qualification for hospital help. Obscure or interesting cases might be sent with a note from the local practitioner when a consultation fee could not be paid. The chief difficulty of any such arrangement is the overcrowding of the out-patients' departments with slight cases which ought to be treated elsewhere. General practitioners are ignored by the hospitals and by too many of their staffs, and the injustice is a trying one. Moreover, the hospitals too often become direct pauperizing influences. There was some discussion of Mr. Hardy's paper in which Drs. Tirard, and Latham, and Mr. Owen expressed more or less agreement as to the abolition of letters, while Sir E. Currie and Mr. Chapman had doubts as to whether it would be possible to abolish letters, and whether the absence of the out-patients' departments was as bad as represented. They deprecated haste and urged further inquiry before coming to a decision.

On Tuesday evening Dr. F. S. Toogood gave an address at the Medico-Legal Society on "Alcoholism and Irresponsibility." The principle of the liberty of the subject had, he said, become in this country, a perfect fetish, and the fear of curtailing his freedom of action let a man inflict the direst injuries on himself and those dependent upon him. The danger of the community to-day was not that sane persons should be confined in asylums, but that insane persons could retain their liberty and involve their families in financial and social ruin. The dread of legal proceedings made doctors reluctant to certify until the facts were so marked as to convince a common jury. Dr. Toogood argued that it ought to be impossible for an inebriate to obtain drink. At present no relief can be obtained by a drunkard's relatives. An ordinary alcoholic was morally, though not legally, of unsound mind, but he did things under the influence of the drug which if done in his sober moments would effectively brand him as insane. The State has admitted the principle of compulsory restraint in the Inebriates' Act. It should make that statute of use by removing the necessity of the inebriate's consent and substitute a form of judicial inquiry.

MEDICAL EDUCATIONAL NEEDS IN KOREA

To the Editor of the Medical Record:

Sir:—Medical fees in Korea depend upon the result of treatment, as in China. No cure, no pay. Improvement in condition is held to merit a moderate recognition on the part of the patient or his friends. Full cure is followed, sooner or later, usually quite promptly, by a gift of rice, eggs, poultry, nuts, fruit, seaweed, or other eatables in quantity according to the circumstances of the family and the service rendered; a money consideration, a pig or two, perhaps so much as a bullock being added in many cases. A prescription of forty ingredients naturally enjoys more popularity among physicians than one of ten, since it commands a higher price, and the doctor is his own druggist and usually gathers many of his own drugs from the three kingdoms of nature. His surgical case contains only a few blades and needles of four-inch length, never washed, always rusty and clotted with the secretions from earlier operations. Commonly they are heated red-hot when used.

This is not an atmosphere congenial to a young doctor educated in an American medical college, nor is he likely to find himself able to exact payment of his bills without regard to the success of treatment. In a country where day's wages range below fifty cents and chairs and bedsteads are a luxury for the very wealthy, a man trained abroad would find medical practice decidedly uphill work.

It is for these and other reasons that it is held necessary to educate in their own country the young men who, in considerable numbers, are now anxious to form Korea's first generation of scientifically trained physicians. The missionary doctors in three or four recently built hospitals are taking hold of the problem and giving to some twenty or thirty such aspirants the best instruction possible with the time and facilities they have at command.

Text-books in the vernacular are indispensable. Dr. O. R. Avison has translated parts of Grey's Anatomy, and has prepared elementary works upon chemistry, physiology, materia medica, and surgery. Botany, practice, obstetrics, and nursing, are subjects that have been taken up by other workers. For lack of funds some of these manuscripts are being duplicated on the mimeograph. That they should be printed and so made serviceable, not alone to the young men under training now in hospitals, but to a coming generation of pioneers of medicine in Korea is a very important ma
interested. It seems a small th
these books should be provided for
America. A committee has been org
pose of receiving funds for this object.

OPEN-AIR TREATMENT OF PN

To the Editor of the Medical Recor

Sir:—Several years ago I read somewh
well-known New York physician (I do not r
said that if he had pneumonia, he would rat
in one of the city parks than in any hospit
The statement has been in my mind ofte
and has helped me to work toward what I consid
pretty sure cure for pneumonia, and if the future proves this to be correct, then what an army of pneumonia patients have died, who might have been saved! Last winter and this I have been treating my pneumonia patients with wide-open windows, but have had some heat in the room also. I keep the windows open in zero weather, both day and night, also when it storms, in fact, all the time until the fever falls. Last winter, during a little blizzard the mother of a young man, sick with pneumonia, closed the window to keep the snow from blowing into the room. The patient at once found difficulty in breathing and insisted on having the window kept open.

I have treated five cases in this way, and all recovered; but it is to describe the treatment adopted in the last case that I write this letter. The patient was a mechanic, aged forty-two years. He had been working from twelve to fifteen hours a day repairing machinery, and to keep going he used liquor very freely. I found him in a very nervous, cyanotic condition, panting for breath, pulse high and jerky, temperature over 104°, respirations irregular, between forty and fifty. Owing to his condition, I thought he had only one chance in ten to recover. The whole right lung was consolidated. I had his bed moved alongside of and close to an open window. I put a quilt from the top of the window to the farther side of the bed, thus making an awning of it, and practically putting the patient's head and chest out of doors. During the night the temperature was down nearly to zero. I covered the affected side of his chest with one of the kaolin preparations. On the fourth day the pulse and temperature fell to normal; the respiration remained high until after the ninth day, but fell slowly during the time. Resolution followed the usual course, but the pulse and temperature remained normal or nearly so.

Warwick, N. Y.

Progress of Medical Science.

Boston Medical and Surgical Journal, March 1, 1906.

Photophobia: a Nasal Reflex.—Edmund D. Spear says that the eye is automatically protected from injury from exposure to bright light, and that it is not the eye alone which produces the symptom-complex known as photophobia. It has been shown that there is a relationship between the so-called erectile tissues within the nose and similar tissues about the ciliary region of the eye. It is a common experience to have a bright light induce sneezing, but the eye is not the real source of the irritation which produces the sneezing. The eye serves to carry the impression to the nerve center; this is transmitted by the sensitive filaments of the fifth nerve in the nose, especially the region above the turbinates, and is sent inward again through connecting ganglia to motor nerves which terminate in the thoracic muscles. The author reports a case of a bell-boy in a hotel who was obliged to await calls in front of a row of arc lamps. He suffered great distress in the eyes. Examination revealed no ocular trouble, but there was obstruction throughout the middle nasal fossa by hypertrophied turbinates. Treatment directed to this part finally relieved the photophobia. The author contends that when light causes one to blink or wrinkle the forehead, the nose is often at fault rather than the eyes themselves.

New York Medical Journal, February 24, 1906.

The Treatment of Joint Tuberculosis in the Open Air in a City Hospital.—R. A. Hibbs refers to two cases of spinal disease with discharging abscesses, both of which steadily deteriorated while in the wards of the hospital. They were then transferred to beds on the roof of the hospital

located on one of New York's densely populated streets, being brought to the ward only a short time each day for the dressing of the abscesses, etc. The change to the roof was at once marked by a vast general improvement in every way. They are still seriously ill, but the author declares that the change has transformed their condition from one of hopelessness to one in which the chances of ultimate recovery are immensely better.

Prostatic Albuminuria.—E. G. Ballinger declares that this form of albuminuria is a not infrequent cause of error in the diagnosis of the so-called orthostatic postural, physiological, and cyclic albuminuria. He concludes that the secretion from an hyperemic or an inflamed prostate is albuminous, while that from the normal gland is not, or is present in such a small quantity that, unless the seminal vessicles are massaged, the urine passed will not give the tests for albumin. This is apparently a constant symptom of chronic prostatitis and may be depended upon in the diagnosis. The periodic increase in the prostatic discharge, along with the striking similarity between the symptoms of intermittent, postural, orthostatic, and cyclic albuminuria, and prostatorrhea makes the possibility of mistakes in the diagnosis extremely likely when this fluid flows back into the bladder and does not appear at the meatus. This regular increase every ten to thirty days, and the analogy between the uterus and the prostate, suggest a relation between the causes of this condition and menstruation.

Rheumatic Fever.—J. V. Shoemaker discusses the etiology and treatment of this common malady. He does not believe that it is, properly speaking, an infectious malady. Although in many instances infections with several forms of pathogenic bacteria may occur, this septicemia is secondary, accidental, and not incidental. Typical cases may occur without it. The blood in acute articular rheumatism is sterile. It may be that certain products of the muscles are a proximate cause of the disease. As to remedies, the author prefers salicin supplemented by local applications of wintergreen oil, the joints being enveloped in cotton and bandaged with flannel. He condemns the use of salicylic acid and all the coal tar derivatives. For accessories he has found the alkalies very useful, especially the citrate of potash in the liquor ammonii acetatis. Some iron preparation is generally required. This may be given separately, as the tincture of the iron chloride or some of the newer combinations, or it may be given at the same time as the alkalies, in the form of Basham's mixture, liquor ferri et ammonii acetatis. When the pulse is rapid and the heart action weak, it is advisable also to combine strychnine with the preceding; or the infusion of digitalis may be given internally, combined with the alkali (such as potassium citrate or sodium bicarbonate) and the strychnine may be given hypodermically, at suitable intervals. For the hyperpyretic cases cold affusions or the cold bath give the best results. The bowels must be kept open, and as the tonsils are doubtless the site of entry of infectious organisms, an antiseptic mouth wash should be freely used. The patient is allowed a moderate amount of food, broths, toast, butter, weak tea or coffee, and an occasional egg. All articles liable to ferment in the stomach should be withheld. Meat is allowed only after the decline of the fever when convalescence seems assured.

Cholecystectomy.—J. F. Erdmann reports twenty-seven cases, analyzing their symptoms and describing the technical details of the operation. Of the entire number all but two recovered. One death occurred in a man of 27 years with thirty-three stones in a distended and elongated bladder, containing typhoid bacilli in the bile, complicated with a diseased appendix containing eleven concretions. The second death was in a man who vomited black matter after the operation. The appendix was removed in sixteen out of the twenty-seven cases. Eight had gangrene of one or more coats of the bladder. The indications and contraindications for the operation are enumerated by the author as follows:—Indications: Perforations by trauma; ulceration other than due to abscess or gangrene (see case of typhoidal perforation); obliteration, or stricture of the cystic duct; chronic cholecystitis with thickened walls; atrophy; gangrene; acute suppuration; enlargement by dilatation; these latter are usually due to either calculus obstructions, strictures or angulations of the bladder, etc.; marked adhesions; hourglass contractions; chronic or recurring cholecystitis, or cholelithiasis and malignancy. Contraindications: Apparently healthy bladder in cholelithiasis and pericholecystitis; perforations into other viscera, when difficulty of closure of the anastomosis is great; perforations in the suppurative variety when adhesions are extensive, and where life would be jeopardized by such radical interference; malignancy when extensive, and those cases where hurried operation is indicated to save life.

Some Difficulties of Diagnosis and Operation in Diseases of the Biliary Tract.—W. P. Carr states that when choleystitis is present in early cases with no obstruction of the bile ducts there are but two symptoms of diagnostic value, pain and tenderness in the region of the gall bladder. Physical signs are usually wanting. Tenderness is of more significance than pain. We are obliged to exclude disease of the stomach, pancreas, liver, pleura, kidney, and appendix and superficial inflammation of the abdominal wall or ribs. The various differential points are enumerated, but in certain affections of the pancreas, liver, and appendix, a preoperative diagnosis is impossible. The greatest difficulty arises in those cases in which disease coexists in two or more of the organs enumerated. Cholecystitis and pancreatitis are often associated as are also cholelithiasis with chronic appendical disease or cancer of the gall-bladder. Carr does not believe that it is possible for the surgeon to ssure himself of the patency of the common bile-duct without opening the duodenum. Excision of the gall-bladder under such circumstances would be unfortunate unless we were assured of the patency of the common duct, and it might prove fatal unless drainage of the duct was provided for at the time. Even if the common duct is open at the time of operation it may become obstructed at some future time in such a way that the obstruction cannot be removed and the gall-bladder will then be of great value for draining the bile into the intestines. Only when malignant disease of the bladder exists is cholecystectomy, in the author's opinion, justifiable.

American Medicine, March 3, 1906.

Cause of Epilepsy.—Otto Lerch advances the theory that the basis of epilepsy is a diseased brain, congenital or acquired. He thinks that the large number of patients in whom a neuropathic constitution and epilepsy can be directly traced, the character of the diseases that cause it, and the large variety of lesions that are found in the epileptic brain prove this proposition. The same train of symptoms occurring under the most varied conditions in patients of all ages uninfluenced by sex, climate, and disease, calls for one direct cause to produce the attack, and this he takes to be congestion and edema. The widely accepted theory of autointoxication he considers with the rest of etiological factors as a remote cause producing congestion and edema.

Chronic Urethritis and an Improved Method of Applying Medication to the Urethra.—E. G. Ballenger says the worst complication that is likely to follow a chronic urethritis is a stricture, consequently this should be borne in mind during the entire treatment. The pathology is essentially a chronic inflammation of the subepithelial tissue (and especially around the follicles) which passes through two stages, that of infiltration and that of contraction. The most rational method of forestalling a stricture is by the treatment of these conditions with the medicated sounds. The ointment may be massaged into the follicles and depressions where the germs are protected from irrigations and injections. The exudation thrown out around these follicles is frequently the starting-point of a stricture. No other single treatment combines so many beneficial factors, *i.e.* dilation, cold, massage and medication uniformly applied to the entire membrane and depressions. The extensive nervous connection and the widespread symptoms that result from injury or disease of the prostatic urethra justify its being called the solar plexus of the pelvis, and many vague, indefinite pains, symptoms, and sexual weakness may often be relieved by the proper medication of this part of the urethral canal.

The Practical Side of Mosquito Extermination.—Henry Clay Weeks discusses the scientific basal work of the entomologists and others; the origin of the practical phase of extermination; the persistency of visionaries; the spread of the idea to large engineering operations; its relation to malaria and yellow fever, its bearing on economic questions such as property values, taxation, scenic improvement, betterment of the poor, etc. He gives illustrations of progress and relief, the success in the New Orleans epidemic from mosquito work and at Panama by Asst. Surgeon Gen. Dr. Gorgas, comparison with other public works in needs, cost, and importance. The reclamation of the Roman Campagna, the outgrowth of the American Mosquito Extermination Society.

Effect of Posture on Cardiac and Vascular Murmurs.—R. D. Rudolf calls attention to the marked effects of posture upon cardiac and vascular murmurs, some of these only being present in certain postures while others are louder in one position than in another. Thus the venous hum, heard in the root of the neck in cases of anemia and various conditions of lowered vasomotor tone, is often only audible when the patient is vertical, while the arterial bruit is often only heard when he is recumbent. As regards cardiac murmurs, it may be generally stated that all systolic ones, if altered at all by posture, are louder in the recumbent than in other postures. Murmurs occurring at parts of the cardiac cycle other than the ventricular systole, if altered at all by posture, are louder in the vertical

than in other positions. The murmurs chiefly affected by changes in posture are the so-called "functional" ones, which are always systolic, and the chief one of which occurs in the second and third intercostal spaces close to the sternum, but posture often has considerable influence upon those due to organic disease. The manner in which posture effects these changes is discussed, and the conclusion is reached that the results are brought about chiefly through the influence of gravity. Dr. Rudolf urges that in every case in which it is considered necessary to auscultate the heart or vessels, this examination should be conducted in both the recumbent and vertical postures; and says that in the description of any heart murmur it should always be stated what postures the patient was examined in when the murmurs were of the nature described.

Journal of the American Medical Association, March 3, 1906.

Goundou and Ainhum.—F. C. Wellman reviews and criticises the various theories of the causation of goundou and ainhum. As regards the former (the African dog-nose disease), he rejects all the theories that have been advanced—that it is due to syphilis or yaws, to atavism, to bony malformations, and to larvæ, all of which, he says, are based only on conjecture. The tumors are doubtless a hyperplasia, probably due to an osteoplastic periostitis with a very definite cause not yet demonstrated. As regards ainhum, he says that no definite and undisputed cause for the lesion has yet been proved, but he thinks that there is most to be said in favor of da Silva Lima's view that it is due to traumatism. The splay-footed negro is especially liable to such, and the groove around the toe in this disease, both macroscopically and histologically, is a cicatrix. The later fatty and atrophic conditions in the amputated toe are not yet fully explained, but may depend on local cicatricial formations or may be of trophic origin.

Tuberculosis and Patent Medicines.—G. R. Pogue thinks that our therapeutic nihilism and teaching that only outdoor treatment is effective for tuberculosis has had a bad effect and has driven many victims of the disease to the use of patent medicines. He was recently told by a prominent pharmacist that while the sale of patent medicines had notably fallen off, he still sold large quantities of certain of them to consumptives. Climatic resorts to which consumptives flock are a bonanza for the advertising quack and patent medicine vender whose stock argument is that physicians admittedly have no cure for the disease as compared with their unfailing panaceas. The poor consumptives are only too ready to grasp at any straw, hence they fall readily into the hands of these quacks. Our therapeutic nihilists, as regards consumption, could do better, Pogue thinks, if they would turn their talents in some other direction when they write for the information of the laity.

Surgical Repair of Injured Nerves.—J. S. Horsley discusses the pathology of nerve degeneration after injury and the regeneration that takes place, especially after surgical union of divided nerves. He holds that, while early operation is advisable in some cases of crushing injuries or when suppuration has occurred, or where there is compression from a callus or a tumor, no operation for nerve suture should be abandoned because of the length of time that has elapsed since the trauma. Cases have been reported in which many years have elapsed between the injury and its surgical repair. He reports at length an interesting case of nerve implantation for complete traumatic paralysis of motion in the forearm except in those parts supplied by the ulnar nerve, and of sensation except in those parts of the skin supplied by the ulnar and musculocutaneous nerves. Two operations were performed, both in the upper arm, with an interval of more than a year between them. In the first operation the median nerve was united to the ulnar, marked improvement following; in the second, the musculospiral nerve was united to the median and fairly good restoration of function resulted. Trophic disturbances, ulcers, and crumpling of the nails of the middle and index fingers appeared, but disappeared after the second operation. The special features of the case are discussed; the facts indicate an anomalous nerve supply for the extensors of the forearm, either a high bifurcation of the musculospiral or a free communication between the anterior interosseous of the median with the posterior interosseous of the musculospiral. The trophic disturbances on the fingers are attributed to an anomalous distribution and partial degeneration of the radial nerve. The article is illustrated.

Spinal Anesthesia by Magnesium Sulphate.—Referring first to the work of Meltzer and Auer on the anesthetic action of magnesium salts, published in the MEDICAL RECORD of December 16, 1905, H. A. Haubold and S. J. Meltzer relate the histories of seven cases in which magnesium sulphate was employed, in solution, by intraspinal injection to produce surgical anesthesia. The authors say: "As far as seven cases permit any conclusions, the following statements may be made: Intraspinal injection of magnesium sulphate is capable of producing anesthesia, and, if carried out with caution, seems to be a safe anesthetic. The following plan would seem the best, at least for the present: To inject about 1 c.c. of a 25 per cent. solution of magnesium sulphate for every 18 or 20 pounds of body weight and wait about two hours. It is probable that by that time the analgesia will be sufficiently advanced to permit the performance of an operation on any part of the lower half of the body. A small dose of chloroform, however, should be administered to divert the patient's attention and to hasten and complete the anesthesia. Immediate washing of the spinal canal should follow the operation in all cases." Further experience will be needed before it is possible to say whether or not the method will serve for general anesthesia in operations on the upper half of the body. The necessity of having the salt chemically pure and the solutions sterile is self-evident.

The Lancet, February 17, 1906.

A Case of Persistent Aberrant Thymus.—The patient of E. W. Sharp was a woman of 22 years who had had a swollen neck for eleven years, the swelling extending from beneath the posterior border of the sterno-cleido-mastoid muscle to the anterior border of the trapezius and passing behind the clavicle. It was removed with some difficulty, owing to adhesions and an extension by a fibrous pedicle into the left posterior cervical triangle. The mass removed was about the size of a potato and had the gross structure of a lobulated gland. The microscope revealed it to be the thymus. The author can find no record in literature of a thymus thus situated. There were no signs of malignancy found, but merely a general hyperplasia of the structure.

A Saccular Dilatation of the Small Intestine.—In a female infant five weeks old with a tumor on the right side of the umbilicus and general stomach and bowel disturbance resulting in death from asthenia, E. Cantley found on autopsy a cyst immediately below the liver, and considerably larger than a normal stomach. It lay in the mesentery and arose from the bowel at a distance of fifteen inches from the pylorus. It communicated with the bowel by two openings. The duodenum and a small part of the jejunum above the origin of the cyst were much dilated and hypertrophied, while below the intestine was thin-walled and collapsed. Opposite the cyst the lumen of the canal seemed somewhat narrowed from pressure, but there was no true stricture. Both cyst and intestines contained normal bile-stained contents. Microscopically, the wall of the cyst was identical with that of the intestine from which it arose, the muscular tissue being considerably hypertrophied. The author admits that the child might have been saved by surgical measures, but he did not feel justified in recommending an operation.

Pneumothorax Due to Muscular Exertion in a Healthy Lad.—W. G. Nash reports the case of a boy of 18 years, who, while stooping over during a football game, felt a severe cramp in the right side of his chest, just below the nipple. It was supposed that a rib had been broken. He had much pain and considerable dyspnea. It occurred to the author that the symptoms might result from lung rupture, as he was able to exclude rib fracture. Four days later all the signs of pneumothorax had appeared. Later the air was drawn off with an aspirator, and the patient recovered without incident. In this case there was no suspicion of tubercle, and there had been no illness likely to cause an emphysematous condition. Moreover, the severity of the symptoms at the outset pointed to a more severe lesion than the rupture of an emphysematous bleb. In the author's opinion the accident resulted from a superficial rupture of the lung near its lower anterior margin. A lung distended from violent exercise, as was the case here, would be more easily lacerated than an empty one. When any part of the lung is suddenly compressed it may burst. In this particular instance it is possible that the engorged lung margin was probably squeezed between the diaphragm lying over the liver and the anterior chest wall. Nash is not an unrestricted advocate of aspiration in most cases, though it was done here. The risk of sudden death from puncture of the chest he does not regard as a negligible quantity.

A Method of Removing Carcinoma of the Ascending Colon.—In the method recommended by F. D. Bird, the abdomen is entered through the sheath behind the rectus internal to the linea semilunaris. The tumor is located, the transverse colon is pulled down and severed between two forceps. The branches of the middle colic artery are secured. This devascularizes a considerable portion of mesocolon which can be quickly severed. Forceps are then placed on the ileum four inches from the junction of the gut with the large intestine, and the gut is divided. The distal end now depends from the wound, so that the whole portion to be resected is hanging by the ileo-colic

artery and some peritoneum. This blood-vessel is ligatured far back, the isthmus of tissue left is divided close to it, and the resected gut, two forceps, and the ileo-colic glands fall out of the wound all together. There is no need to investigate the important ileo-colic lymphatic area, for it has gone, but the mesocolic region should be examined for glands which may have escaped the section. Thus four, or at most five, arteries have to be tied; the transverse colon is divided at right angles to its lumen, but the ileum, if it approaches the caliber of the colon closely enough to allow of apposition, is severed in a direction obliquely downwards to the mesenteric attachment, which, of course, increases the size of the open end. If the disproportion be too great the ileum is also separated at right angles, the patent lumen to be afterwards applied by means of temporary sutures to an incision proportionate in length in the fundus of the colon about two inches from the gaping end, through which the stay ligatures are pulled, reversing Maunsell's method, and the new ileo-colic junction is quickly made by through-and-through sutures, to be reinforced after the ileum is pulled back by a continuous Lembert suture. The end of the colon being closed, the operation, but for ordinary detail, is completed.

British Medical Journal, February 17, 1906.

Some Abdominal Disorders which Resemble in Their Symptoms Acute Intestinal Obstruction.—After an enumeration of the classical features of acute intestinal obstruction, G. Heator declares that they may be simulated by the following conditions, respectively: Biliary or renal colic, perforative peritonitis due to the rupture of a gastric or duodenal ulcer, gangrenous appendicitis or ruptured appendix abscess, tuberculous peritonitis, acute hemorrhagic pancreatitis, torsion of an undescended testis or relation of an ovarian cyst, rupture of an ectopic gestation, and embolism or thrombosis of the superior mesenteric vessels. Illustrative cases are given under several of these headings. The author notes that the intestinal walls are so delicate and their nervous supply so intricate that any interference with their vascularity or the free flow of their contents may in a short time produce such pathological changes as almost to preclude restoration of function, even though the cause of the trouble may be removed. Hence comes the urgency of a rapid and accurate diagnosis. We cannot "watch the case," and so deliberately decide upon the preferable course to pursue. Therefore mistakes in diagnosis not infrequently occur, and one must often adopt measures based upon what is at the most but a provisional opinion rather than run the risk of allowing an acute obstruction to remain unrelieved.

Stagnation of Food in the Stomach.—A. McPhedran discusses some of the questions bearing on the relation between gastric and intestinal digestion. It is now known that under the stimulus of the acid of the chyme the duodenal mucosa elaborates a substance which is the stimulus causing the pancreas to pour out its peculiar ferment. As soon as the chyme is neutralized the secretive elaboration is checked. Duodenal peristalsis has by this time carried it on into the small bowel. Then the pylorus relaxes to allow more chyme to pass through, and the process above outlined is repeated. The chymification of an ordinary meal requires from six to seven hours. When this is delayed we have one of two conditions at work: First, deficient gastric expulsive power, or, second, abnormal difficulty of the passage of food through the pylorus. Probably the most common cause of deficient expulsive power is the overloading of the stomach with food; especially food not properly masticated. Those who thoroughly chew their food rarely overeat. Pyloric obstruction may be spasmodic or organic. The only positive symptom is vomiting; all the others are indefinite. Treatment calls for recognition of the main principle that the stomach must empty itself within the normal period. This implies the careful regulation of dietetic hygiene, especially the ingestion of food proper in character, and always thoroughly masticated. Baths, douches, compresses, and massage are all valuable adjuvants. Drugs are of little use. Bitter tonics and stimulants often aggravate the condition. Sedatives and antiseptics are preferable. Shontium bromide has proven of especial value. The natural sodium salicylate is also of service. In cases due to pyloric obstruction we should not be too hasty in resorting to surgery. We should make an effort to lessen the acidity by giving a liquid or very soft diet free from particles and irritants, and the use of antacids for the relief of pain and the lessening of excessive acidity. Regular lavage should be done for a time if there is material retention, and, after emptying the stomach, some sedative, as bismuth subcarbonate in full doses, may prove useful. Large doses of pure olive oil are often of benefit in soothing the stomach; they have the effect, also, of lessening the secretion of acid (Pawlow). If necessary, rectal feeding may be depended on for a short time, and then a gradual return made, first to a liquid diet, and later to solid food.

Obstruction of the Bowel Produced by the Appendix.—The patient of R. W. Leeming and M. I. Dick was a boy between four and five years of age with evidences of bowel obstruction calling for operation. The small bowel was traced to the seat of obstruction, but this point was fixed and the gut could not be followed up further. The median incision was extended to above the umbilicus when the part between the distended and collapsed bowel was found. In this position, on one side of the bowel, was a tumor about the size of a walnut, white, and apparently full of fluid. On the opposite side was a narrow piece of bowel apparently knotted to the small bowel. A careful examination showed that the narrow piece of bowel was the appendix, which had passed over the bowel itself and then through a hole in the mesentery, and the white tumor was the constricted end full of secretion, etc. The end of the appendix was removed and the obstruction cleared. The patient, however, unfortunately sank from shock.

Antidiphtherial Serum by the Mouth.—A. M. Pilcher has the greatest confidence in the oral administration of this remedy, provided there is no violent urgency present at the time. The stomach must be empty and vomiting absent. A list of thirty-eight cases is tabulated, all but two of which gave prompt results. In one the administration was apparently without effect, though the child recovered. In only one instance was this method supplemented by that of injection, laryngeal symptoms having come on suddenly during the night.

Berliner klinische Wochenschrift, February, 12, 1906.

Parasites in the Blood of a Case of Yellow Fever.—Schüller rehearses the long list of parasites which different observers have described as occurring in the blood of this disease and adds a fresh one of his own to the number. The material he worked on consisted of two slides sent to him from the New Orleans epidemic at the instigation of Dr. Wyman. The author notes that the average size of the red corpuscles of the yellow fever blood was increased to a diameter of from 8-10 μ. In addition considerable numbers of especially large red corpuscles were found which exhibited irregular, thin edges. Other peculiarities in color and conformation of the erythrocytes are also noted but the author's most striking observation is concerned with the identification of certain bodies which he considers may be regarded as parasites belonging to the sporozoa. He describes and illustrates many different phases in the life history of this putative organism, and asserts his belief that the sporozoites or merozoites of the parasite invade the red corpuscles and either destroy it directly or after further stages of development of the organism have taken place in the interior of the cell. The organisms appear to be present in the leucocytes also. Spirochetes, which do not, however, resemble those of syphilis were also found in the preparations, but the author does not draw any conclusions from their presence.

Münchener medizinische Wochenschrift, February 13, 1906.

A Clinical Test for Fat in the Feces.—Hecht describes the following procedure for making quantitative determinations of the fat in the feces. About 10 c.c. of the stool are placed in a wide-mouthed flask of about 300 c.c. capacity and a small piece of potassium hydrate and enough water to cause liquifaction are added. The flask is then warmed on the water bath, and after ten minutes about 100 c.c. of 96 per cent. alcohol are poured in and the heating is continued for twenty minutes longer. A funnel placed on the flask serves as condenser. The mixture is acidified with concentrated hydrochloric acid, using as indicator a few drops of a 1 per cent. alcoholic solution of alkali blue, and is filtered into a porcelain dish, the filter being washed with a little additional alcohol. The alcohol is then driven off on the water bath, which takes about an hour, and the residue is dissolved in as little ether as possible and is filtered into a special flask which is so made in two parts, the upper of these being a narrow graduated tube. The ether is evaporated by heat and enough hot water is poured into the flask to cause the fatty acids to float up into the graduated portion of the tube where the amount of fat may be directly read off from the scale.

The Production of Satisfactory Milk for Infants and Invalids.—Hempel describes the methods by means of which it has been found possible at a special dairy to produce regularly milk having only about 1,600 bacteria to the c.c. This is effected by the most scrupulous asepsis in every detail of its collection. The cows are milked in a separate building having no connection with the stable, the animal's tail is tied out of the way, its abdomen is covered with a large apron of linen which leaves only the udder exposed, the milker wears a clean suit of white linen, and the udder is always washed before each milking. The milk is received in a sterile funnel placed in a covered sterile tin bucket. The author considers it of importance not to shake the

milk at any time, as this would tend to break up any existing colonies of bacteria, thereby facilitating their multiplication, and he has devised a special form of outlet tube for milkpails, etc., by means of which it is possible to draw off milk of homogeneous composition without any preliminary shaking. The bottles used for distribution are made without sharp angles and are closed with ground-glass stoppers; they are sterilized before use, and immediately after filling are cooled to 5° C. The author points out the changes in the point of view in regard to milk which have taken place since it has come to be recognized that sterilized milk is very inferior as a food and affords a much more favorable nutrient medium for bacterial growth than is the case with raw milk, and emphasizes the necessity for the further development of the dairy industry along the lines suggested.

The Poison of Eclampsia and Its Effect on the Treatment.—Zweifel relates the theoretical considerations which induced him to take up the investigation of the blood and urine of eclamptics with the expectation of finding sarcolactic acid present in both. Sarcolactic acid is produced in animals subjected to the influence of an atmosphere containing much less than the normal amount of oxygen, but is not present in the blood or urine of healthy human beings or animals under ordinary conditions. The author states that the detection and positive identification of sarcolactic acid in the urine is extremely difficult, but he was able to demonstrate its presence in the urine of eighteen successive cases of eclampsia. Furthermore, on examining placentas and the blood of the umbilical cord, it was found that in seven cases the proportion of sarcolactic acid was greater than it was in the maternal blood. The author points out that this theoretical consideration affords confirmation of the dictum which has already been deduced from practical experience, that the uterus of an eclamptic patient should in every case be emptied as promptly as possible, since it appears that the child is a source of manufacture for the deleterious sarcolactic acid. He also emphasizes the necessity for frequent examinations of the urine during the last three months of pregnancy, and points out that no symptoms such as headache, vomiting, or ocular disturbances should be overlooked. Zweifel does not believe in the use of morphine in eclampsia, and also expresses the view that treatment by hot packs and other sweating procedures is not only useless because it does not eliminate any poison, but is also directly injurious, since it concentrates the blood. On the other hand, bleeding followed by infusions of salt solution or of solutions containing one-half per cent. of sodium chloride and one-half per cent. of sodium bicarbonate represents a very valuable therapeutic measure. Another procedure of great value is gastric lavage. The vinegar of digitalis and the vinegar of squill are also recommended for their effect on the heart and urinary secretion.

Deutsche medizinische Wochenschrift, February 15, 1906

Are the Hemolytic Immune Bodies or Complements Ferments?—Liebermann is of the opinion that the immune body and complement do not belong to the class of the ferments; that is, that they are not substances which bring about reactions between other bodies without being directly concerned in the reaction themselves. He experimented on the hemolytic substances by adding to definite quantities of an emulsion of red blood corpuscles, first, definite quantities of inactivated immune serum followed by increasing amounts of complement, and, second, fixed amounts of complement followed by increasing amounts of inactivated immune serum. If these bodies were ferments in either case the amount of lysis of the red blood cells produced would increase in proportion as the amount of complement or of immune body respectively was increased in the two experiments. By determining the amount of hemoglobin present in the supernatent fluid by means of Fleischl's hemoglobinometer it was found that a fixed degree of lysis was soon reached which was not increased by further additions of the respective substances, so that the author feels justified in concluding that they are not ferments. This observation has a practical bearing of considerable importance in the matter of producing artificial immunity, as if the substances concerned were ferments it would be necessary to introduce only a certain quantity sufficient to induce satisfactory activity of reaction, but if they are not ferments much larger quantities must be used.

The Increased Arterial Pressure of Arteriosclerosis and Its Treatment.—Erlenmeyer attaches great importance in the treatment of arteriosclerosis to the reduction in the viscosity of the blood following the use of potassium iodide. This drug, by diminishing the frictional resistance of the blood current, gives rise to better nutritive conditions in the diseased districts, and it is to this property rather than to any reduction of blood pressure *per se* that its value in the treatment of arteriosclerosis must be ascribed. The author is in accord with the view of Krehl, that the rise of arterial pressure in arteriosclerosis may be the result of an attempt of the organism at self-treatment in the sense of its opposing the influences causing the disease. In cases of arteriosclerosis in which an increase of arterial pressure cannot be demonstrated its therapeutic increase is carefully to be effected. In doing this carbon dioxide brine baths at a temperature of 30° C. or less, are to be recommended. In cases with moderate increase of arterial pressure the viscosity of the blood should be reduced by progressively increasing amounts of potassium iodide continued over long periods of time. If the rise in blood pressure is great, small repeated phlebotomies must be resorted to in order to avoid the danger of vascular rupture, while at the same time the potassium iodide treatment is being begun.

Antefixation of the Uterus and Protracted Gestation.—Ahlfeld, who himself does not very often carry out ventro- or vaginifixation of the uterus, cites two cases of his own as well as a number of others from the literature which corroborate his theory that these operations conduce to an abnormally long period of gestation. Both of the author's own cases had had a ventrofixation done, and the pregnancy of the one extended from the middle of May to the 19th of March, and that of the other from the 26th of March to the 10th of January. In explanation of this tendency to protracted gestation the author suggests that through the abnormal direction of the uterine axis the presenting part is not so effectual in dilating the upper cervical segment as it should be, and as this latter action is supposed to be an important factor in inducing the onset of labor, pregnancy becomes unduly protracted under these conditions. Ahlfeld urges obstetricians attending the confinements of women who have been subjected to operations of this sort to publish data concerning the duration of pregnancy.

French and Italian Journals.

Syphilis of the Liver.—M. J. Milhit declares that the prognosis of hepatic syphilis varies according to the extent of the lesions. The prognosis should be guarded on account of lesions, especially renal, which often accompany and complicate this disease. Specific treatment is indicated,—injections of mercury biniodide associated with large doses of iodide. Certain authorities have advocated the application of a mercurial pomade over the region of the liver. Under the influence of specific treatment, slight congestions and simple jaundice disappear rapidly. In severe jaundice the treatment has no effect. In cirrhosis, considerable diminution in the size of the organ may be obtained. But very often the treatment is powerless to modify the lesion, either because it is too far advanced and the cirrhosis too well organized, or because there exists already amyloid degeneration, or because, perchance on account of secondary infections. The mercurial treatment should be followed up for a long time, and lack of success ought not to be taken as a proof that there is an error in diagnosis. The late visceral manifestations of syphilis are well known to be refractory to specific treatment. Together with the mercurial treatment the patient should be subjected to the régime for hepatic diseases. A prolonged milk diet is of great value. Renal complications may demand special treatment. Surgical treatment should be absolutely rejected.—*Gazette des Hôpitaux Civils et Militaires,* January 20, 1906.

New Technique in Mikulicz Resection of the Tarsus, After Padula.—Vincenzo Marcozzi describes the operation in a case of tumor of the astragalus, in which a modification originated by Padula of the Mikulicz resection of the tarsus was successfully undertaken, the results to the patient being most satisfactory, as he was able to walk well and easily without much of a limp. The patient had a sarcoma of the ankle, which began in the periosteum of the calcaneum, and was propagated to the other bones and to the skin. The conclusions given by the author are these: 1. The operation of Mikulicz is the best that can be used for resection of the bones of the tarsus and lower extremity of the leg. 2. Besides the astragalus and calcaneum, when necessary the cuboid and scaphoid may be removed without destroying the good functional results of the operation. 3. It is indicated for lesions of the tarsus and lower part of the leg, and of the skin and other tissues of the calcaneum when new growth or ulceration prevents healing. 4. The new incision of Padula through the soft parts avoids all the necessary structures, such as veins, arteries, and nerves, and gives the best results as to function. The incision begins at the anterior margin of the external malleolus, passes horizontally backward to the inner margin of the tendo Achilles, is prolonged with a slight lateral inclination down to the base of the heel, passes obliquely across the sole to the outer margin of the foot, behind the tubercle of the fifth metatarsal bone, and rejoins obliquely the original line at its beginning.—*Giornale Internazionale delle Scienze Mediche,* January 15, 1906.

Book Reviews.

Genitourinary and Venereal Diseases. By J. William White, M.D., John Rhea Barton Professor of Surgery, University of Pennsylvania, and Edward Martin, M.D., Professor of Clinical Surgery, University of Pennsylvania. Illustrated with 300 Engravings and 14 Colored Plates. Sixth Edition. Philadelphia and London: J. B. Lippincott Company, 1905.

A colored plate, opposite the title page, showing a number of highly-stained specimens of *Spirochæta pallida*, assures the reader of this new edition of White and Martin's standard work that it has been brought up to date; but the plate is newer than the text, for in the section on Syphilis, there is no mention of Schaudinn's alleged discovery of this spirochete, and nothing on the subject whatever beyond the statement that "syphilis is almost certainly due to the presence in the system of a specific microbe." It would be unfair to demand that a book which came out at the end of 1905 should contain an account of this discovery, for the revision of this part was no doubt completed and in type before anything definite was known regarding it; but this lack might have been supplied by a page inserted with the plate at the beginning of the book. As it is, one is led to expect too much, and is correspondingly disappointed in turning to the text for an explanation of the plate. This, however, is a minor point, and does not affect the value of the work as a thoroughly trustworthy guide in the diagnosis and treatment of diseases of the genitourinary tract. The text is clear and explicit, and the illustrations are numerous and well made. The greatest number of changes in the present edition are to be found, as one would naturally expect, in the section on diseases of the prostate gland. Minor changes have been made in other sections wherever necessary to bring the work abreast of the times and to keep it, where it has always stood since the appearance of the first edition, in the front rank of authoritative text-books on the surgery of the genitourinary system.

Saunders' Question Compends. Essentials of Materia Medica, Therapeutics, and Prescription Writing. By Henry Morris, M.D., College of Physicians, Philadelphia. Seventh Edition, Thoroughly Revised. By W. A. Bastedo, Ph.G., M.D., Instructor in Materia Medica and Pharmacology at the Columbia University (College of Physicians and Surgeons), New York City. Philadelphia and London: W. B. Saunders & Company, 1905.

In the new edition of this compend, the definitions, nomenclature, preparations, and doses have been made to conform with those of the recent revision of the U. S. Pharmacopeia. There also appear for the first time sections on diphtheria antitoxin, organotherapy, and thyroid extract. As a compend on Materia Medica it can hardly be improved.

Anatomy, Descriptive and Surgical. By Henry Gray, F.R.S., Fellow of the Royal College of Surgeons; Lecturer on Anatomy at St. George's Hospital Medical School, London. Edited by T. Pickering Pick, F.R.C.S., Consulting Surgeon to St. George's Hospital and to the Victoria Hospital for Children, London; H. M. Inspector of Anatomy in England and Wales; and Robert Howden, M.A., M.B., C.M., Professor of Anatomy in the University of Durham; Examiner in Anatomy in the Universities of Durham and Edinburgh, and to the Board of Education, South Kensington. New American Edition. Thoroughly revised and re-edited with additions by John Chalmers DaCosta, M.D., Professor of Principles of Surgery and Professor of Clinical Surgery in Jefferson Medical College, Philadelphia; Surgeon to the Philadelphia Hospital; Consulting Surgeon to St. Joseph's Hospital. Illustrated with 1,132 elaborate engravings. Philadelphia and New York: Lea Brothers & Co., 1905.

The present edition of Gray's Anatomy has undergone a most thorough revision. The special sections on Histology and on Embryology have been omitted, but résumés of these important subjects have been interpolated in their proper place in the text whenever necessary. With this exception, the general arrangement has not been disturbed. The chapters that have received the most radical revision are those on the Lymphatic System and the Nervous System. The former of these now gives a most satisfactory account of the present knowledge of the subject. The chapter on the Nervous System is a great improvement on that in some recent editions; and, besides being accurate and sufficient, is also readable and interesting. The illustrations, which have always been a feature of this work, now number over eleven hundred, and about half of them are new in this edition. Both text and illustrations have been enriched from all available sources: and by omissions, alterations, and additions, almost every page bears witness to the judicious work of the editor. The printing, paper and general get-up of the book are all that can be desired. It is difficult to say which excites the greater admiration, the vitality of the original work of Gray, which has been able to survive so many editions at the hands of so many editors, or this newest American edition, the able editing of which insures this classic a continuance of its position in the forefront of books for the student and the practitioner. An anatomy is the first book for the medical student to buy, and the last for him to part with.

Blakiston's Quiz Compends. A Compend of Medical Chemistry, Inorganic and Organic, Including Urinary Analysis. By Henry Leffmann, A.M., M.D., Professor of Chemistry in the Woman's Medical College of Pennsylvania, and in the Wagner Free Institute of Science. Fifth Edition, Revised. Philadelphia: P. Blakiston's Son & Co., 1905.

The previous edition of this compend was issued eleven years ago. In the new edition are a few changes, notably the addition of paragraphs on the electrical relations of the elements, and on the classification of the elements. The sections on vegetable chemistry and part of that on animal chemistry are omitted. The misplacement of figures in the table of the composition of milk may prove misleading. The book is weak in definitions. The word "Medical" is inserted in the title of the book, and is upheld in the preface, but we fail to find any material changes in the text to justify the addition.

Opérations Plastiques et Anastomoses dans le Traitement des Rétentions du Rein. Par le Dr. Faxton E. Gardner, Ancien Interne des Hôpitaux de Paris, et de la Clinique des Maladies des Voies Urinaires de l'Hôpital Necker; Médaille de Bronze de l'Assistance Publique. Paris: Vigot Frères, 1904.

This book is a contribution to conservative renal surgery. After a short historical introduction, the author describes the technique and results of the various operations referred to in the title. The indications for these operations, and also their contraindications, are next discussed. The author then gives a series of fifty-nine cases treated on the lines advocated; these cases are chiefly collected from the literature of the subject, but some of them are here published for the first time.

Immunity in Infective Diseases. By Élie Metchnikoff, Foreign Member of the Royal Society of London; Professor at the Pasteur Institute, Paris. Translated from the French by Francis G. Binnie, of the Pathological Department, University of Cambridge. With 45 Figures in the Text. Cambridge: The University Press; New York: The Macmillan Company, 1905.

The original of this translation appeared in French in 1901 and summed up, the author says, the labors of twenty-five years. Since its publication the lore of immunity has been increased by many new observations, and it now appears that the doctrine of phagocytosis, which at first was in many quarters regarded in this connection merely as the *jeu d'esprit* of an imaginative zoologist, is destined to play as important a rôle in the theories of immunity as its originator had prophesied for it many years ago. As Metchnikoff takes pains to explain, there is not that radical discrepancy between his own views and those of Ehrlich which is often alleged, the differences being mainly those of the two standpoints from which the subject may be attacked. Metchnikoff's theoretical edifice is founded on the observations of the biologist, while Ehrlich interprets the same phenomena in terms of chemistry. The doctrines of the side-chain theory are entirely compatible with the results obtained by Metchnikoff, the only vital difference of opinion between the two schools being concerned with the habitat of the cytolytic and bacteriolytic ferments, or cytoses, under normal conditions. Ehrlich supposes them to be always free in the body fluids, whereas Metchnikoff contends that they are constituents of the phagocytes and are liberated only when in response to a stimulus of some sort phagocytolysis occurs. According to his belief, phagocytes may be free or fixed. The former are cells of the circulation and comprise the microphages or polymorphonuclear leucocytes, and the macrophages or large mononuclear cells. The fixed phagocytes are tissue cells, occurring in nearly all parts of the body, and closely resemble or are identical with the free macrophages. The microphages are the particular enemies of invading bacteria, while the macrophages destroy foreign cells of animal origin. The ferments or cytases of these cells which permit this action may be set free in the body fluids if the phagocytes are damaged, and may then be experimented with in the manner described by Ehrlich and his followers. It is impossible in a brief review to do more than sketch the barest outlines of the fascinating study which the brilliant Russian *savant* has elaborated, and as the translator has done his work so well that much of the vivacity of the original has been preserved, we can only commend the volume most heartily to those who would regale themselves with a scientific work of the highest importance, which is as agreeable to read as one of the "six best sellers."

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

Regular Meeting, Held February 1, 1906.

DR. CHARLES L. DANA IN THE CHAIR.

THIS meeting was held under the auspices of the Section on Otology.

Intracranial Lesions as Sequelæ of Chronic Purulent Otitis Media.—Dr. M. ALLEN STARR read this paper. (See page 369.)

Otitic Disease in its Relation to Intracranial Lesions.—Dr. CLARENCE JOHN BLAKE of Boston said that the diseases of the ear, precedent to intracranial disease of otitic inception, were mainly those which had their origin in an infection, and the character of this infection, the extent of tissue destruction accompanying it, the systemic condition of the patient accompanying it, with reference to the capacity for affording not only eliminal but also mechanical resistance to the extension of a suppurating process, as well as the contiguity of the otitic and cranial cavities and the character of their encapsulation had to be taken into consideration in the study of this subject from the otological point of view. He described the anatomy of the tympanic space, tympanum and post-tympanal bone in the infant and the adult and showed that the frequency of post-aural and progressive interlamellar osteomyelitis of the post-tympanal bone and squama, as a sequence of suppuration within the middle ear in the infant, was accounted for by the loose relationship of the individual bony parts. While the progressive developmental changes in the epitympanum and the mastoid, and in their cortical walls, presented a certain definable sequence, a comparison of the developed spaces in different adults showed such a difference in contour and in structure as to justify the assertion that there was no one bony structure in the human body which presented so many deviations from an arbitrary standard type as the normal epitympanum and mastoid process of the temporal bone. The same multiplicity of variations was found on the inner walls separating the mastoid from the cranial cavity. The primary inceptive changes in the tympanic mucous membrane, preliminary to a suppuration, were those of a serous exudative process which became characteristically altered by the presence of pus-producing bacteria. The microorganisms found in the pus, in cases of suppurative middle-ear diseases were numerous, the most important being the diplococcus of pneumonia, streptococcus, pyogenes albus and aureus, Friedlander's bacillus, the bacilli of diphtheria, tuberculosis, influenza, and pseudoinfluenza, the *Bacillus pyogenes*, *Bacillus fœtidus*, and *Bacillus coli communis*. In children the pneumococcus was isolated in pure culture more frequently than other organisms, the streptococcus coming second, and the staphylococcus third. In chronic suppurative cases a mixed infection was the rule. When suppuration broke through tympanic bounds the problem became a serious one, and it was by extension from the tympanum, epitympanum and mastoid that lateral sinus thrombosis, extradural abscess, cerebral and cerebellar abscess and meningitis ensued. The sequence of the extension of septic inflammatory process from the epitympanum to the mastoid cavity was first, through the connecting pneumatic cells, extending thence to the surrounding diploe and finally to such portions of the epitympanum and the mastoid cortex as might be more vulnerable. The less resistant cortical areas were usually found where the cortex was thin. The limitation of pus collections was determined largely by the mechanical resistance of the surrounding tissues, by the influence of gravitation and by the controlling effects of a secondary inflammatory process. A normal and constantly persistent mechanical agent for protection of the cranial cavity from invasion was the outward brain pressure, downward upon the superior and outward upon the posterior inner mastoid wall. When the extradural abscess had persisted for a sufficient length of time the exposed dura would be found covered with granulomata. In such instances the dura should be freed from granulomata by careful blunt curetting and dry scrubbing, care being taken not to penetrate laterally beyond the limit at which the adherence of the dura marked the boundary of the abscess cavity or to penetrate the dura itself. One of the complications to be looked for, especially in cases of prolonged suppurative disease of the mastoid was the implication of the lateral sinus, either by inflammatory thickening of its wall and consequent decrease in the lumen of the vein, or by formation of protective thrombus. The initial point of this invasion was usually upon the posterior mastoid wall, though it might also occur on the posterior superior mastoid wall. The thrombus might be either a flattened mural or it might entirely fill the lumen of the vein and extend downward to the entire occlusion of the jugular vein. In this case it was readily revealable by the general train of symptoms. He emphasized the importance of early operation in these cases, when once the suppurative character of the inflammatory process had been definitely determined and also, the importance, in all doubtful cases, at time of operation, of uncovering the sinus to a sufficient extent to permit free visual and tactile examination of the vein. Normally the vein should show a dark blue color, should be easily compressible by the finger, and a bent probe, with the convexity of the curve pressed across the vessel, should exhibit a flattened surface of the vein below and a convex surface above it. In the event of inflammatory thickening of the vessel wall, the deep blue color was lost and tactile examination was insufficient to descide between the resistance offered by a thickened vessel wall or an occluding thrombus, in which case the question must be answered by opening the sinus itself. A narrow bladed knife or straight manicure scissors were preferable to the hypodermic needle. If the thrombus was septically intact it might be curetted above until free bleeding had established effective lavage. Ligation of the jugular was not essential in all cases of sinus thrombus. The operation of ligation of the jugular alone, or when coupled with resection of the thrombosed vessel above the point of inferior ligation, was simple and secure, and there were as yet no evidences of prejudicial effects. In regard to extra and intradural and brain abscesses the general course to be followed in a case of suspected brain abscess of otitic origin should be first, the observance of all possible peripheral localizing symptoms and second, as complete an operative exposure as possible of the tympanic and mastoid cortical walls with a view to following surgically the course of septic infection. For this purpose the tympanomastoid exenteration was the most effective preliminary operation. The lymphoid encapsulation should be distributed as little as possible, consistent with free clearance of the abscess contents. In addition to drainage, lavage of the abscess cavity with warm, normal salt solution, under slight pressure, should be practised at the daily dressings unless contraindicated by immediate pressure symptoms or symptoms of cerebral irritation. With an intimate knowledge of the minute structure of this chosen field the aural surgeon had a primal duty in the prevention of intracranial complications of suppurative middle-ear disease. He emphasized the necessity of making as complete operative exposure of the possible paths of infection as possible and of limiting interference with the dura and brain substance to the degree of a safely indicable and rationally predetermined procedure. In regard to labyrinthine suppuration he said that in the light of recent knowledge the diagnosis of these suppurations would be facilitated, but the actual number of cases would probably decrease because of improved methods of treating middle-ear disease. The most reliable statistics indicated one case of labyrinthine suppuration in one hundred cases of purulent middle-ear disease. The reader of the paper described the etiology and pathology of this condition. The prognosis was a grave one, owing to the frequency of its complication with suppurative menin-

gitis. Surgical measures afforded the only hope of satisfactory treatment. The operation should consist of a complete mastoidtympanal exenteration and a sufficient area of the outer surface of the temporal bone should be removed to permit a clear view under illumination, of the internal tympanic wall. When caries of the labyrinth wall was found, a thorough opening of the labyrinth and the following of the suppurative tract would secure the best results. Fairly satisfactory results would follow thorough surgical treatment even in cases where serous meningitis had been previously established. No attempt should be made to secure primary closure of the post-aural wound.

Dr. B. Sachs said that for many years he had been in the habit of speaking of these cases as the result of meningeal irritation when in connection with ear diseases. The treatment of encephalitis seemed to him to depend upon whether the encephalitis was of the acute hemorrhagic or the suppurative variety. With regard to the diagnosis of temporosphenoidal abscesses the form of the aphasia struck him as being rather charaeteristic. It was not the aphasia one would expect; pure sensory aphasia was the exception. He said he could not recall a purely sensory aphasia as a sequel of otitic infection. With regard to cerebellar abscesses, cerebellar seizures pointed to a cerebellar involvement; in cerebellar seizures there was a distinct grouping of symptoms, pointing to involvement of the cerebellum; the symptoms which helped to locate the abscess in the vicinity of the cerebellum was the early involvement of the facial nerve, not in the way of a paralysis, but of electrieal degeneration. Brain surgery was not as satisfactory as it should be in this country and surgeons in this country were behind those abroad in this branch of surgery, and particularly were they neglectful in the avoidance of hemorrhage. He did not believe in draining brain abscess through the ear; the brain was such a delicate organ that nothing should be attempted in the dark.

Dr. George W. Jacoby said that the more he had listened the more he had been convinced that, notwithstanding all that had been said regarding the differential diagnosis between epidural and intracranial abscesses and different forms of meningitis, it was still a difficult matter. He then called attention to a point that he did not believe had received the attention it should have, which was serous meningitis complicating otitis media. During the course of an acute otitis there was a sudden acute onset of symptoms pointing to brain pressure, accompanied by reduction in vision, optic neuritis, and cerebellar symptoms. In such cases the diagnosis of suppurative meningitis or brain abscess was usually made. A puncture was made, but nothing found, yet the patient then improved and got well. In such a case, he said, they were dealing with this form of meningitis, a serous meningitis, and the opening, as by a puncture, was followed by a cure. In these cases the pressure was mostly in the posterior fossa, accounting for such symptoms. The results of lumbar puncture, evacuating a clear fluid without microorganisms or cells, were good. The symptoms resulted from the high pressure. Therefore in doubtful cases he believed in employing lumbar puncture with drainage; if no fluid was obtained he then advocated opening the ventricles of the brain, performing puncture in that way. He believed blood examinations were very important, especially noting the increase in the polymorphonuclears.

Dr. Hermann Knapp called attention to the fact that brain abscess situated in the anterior fossa resulted from conditions within the nose or sinus; in the middle portion, from the mastoid or tympanic cavity; in the posterior fossa it was the result of a pyemic process which came from the sinus. In the treatment of these abscesses he believed failure very often resulted from too small an opening. In cases of epidural abscesses large incisions should be made, and not mere punctures.

Dr. Edward B. Dench said that he had operated upon a case of septic encephalitis with a perfect recovery following. Blood count in brain abscesses as a diagnostic measure he believed of great value, especially the polymorphonuclear count. He did not entirely agree with the statements made regarding leucocytosis except that it was moderate in cases of thrombosis of the jugular vein. It was his personal opinion that otologists should operate upon these brain abscesses of otitic origin, and that they should enter above the zygoma. With regard to a bone flap he believed that it was better to make a large opening, and then, at some later period, fill in that opening with a celluloid plate or connective tissue. In sinus thrombosis one almost always found some thickening, but there was, in some cases, a rapid breaking down of the abscess. With regard to the ligation of the jugular vein he did not believe this was necessary in all cases; but he did not believe in ligating it and then leaving it *in situ*.

Dr. James F. McKernon said that the *x*-ray had been used in the clinics at Bordeaux, and also at Vienna, with varying successes, and that he himself had used it in two cases, in which only one was positive. The pus was where the radiograph showed it to be. He thought that in the future the radiograph might help them in the diagnosis of brain abscesses very much. With regard to the contraindications of the iodoform drain, as mentioned by Dr. Starr, in brain abscesses, he said he did not believe that anyone had better results than Maeewen, and he used gauze impregnated with equal parts of borie acid and iodoform, packing it in loosely. Dr. McKernon had used this method with uniformly good results. With regard to irrigating the brain abscess eavity with hot physiological salt solution, he said he advocated this in cases of brain abscesses eight or nine years ago, and had been severely criticised for attempting to irrigate an abscess cavity in the brain. The polymorphonuclear blood count had helped him considerably in diagnosing epidural abscesses and sinus thrombosis and was one of the most valuable adjunets in diagnosing these cases. Again, in every case of intracranial complication the time element entered largely in the successful issue of these cases.

Dr. T. P. Berens believed that the future in this eountry would develop specialists in brain surgery.

Dr. Sprague of Providence, R. I., reported two cases of suppurative meningitis which were of partieular interest when the blood count was studied. One was a mastoid ease showing the whites to be 20,000 and the polymorphonuclears 04 per cent. After the operation the patient did well for six weeks, when she was taken with nausea and persistent vomiting, with a rapid rise of temperature, and died after two or three days of meningitis. At autopsy there was found a widespread meningitis. Forty-eight hours prior to death the white eount was 28,000, while the polymorphonuclear percentage remained the same. The second case was one of suppurative meningitis and showed similar conditions at autopsy. During the illness the white count did not go above 7,500 and the polymorphonuclears amounted to 70 per cent. In another ease in which he had operated the white eount was 10,000 and then suddenly went up to 30,000. The brain was probed and half an ounce of pus was evacuated.

Dr. William M. Leszynsky said he had observed a case which illustrated the extreme diffieulty in coming to any definite eonclusion in diagnosing brain abscess. The patient had been operated upon for mastoid disease of suppurative type and then soon developed signs of meningitis. Lumbar puncture was done and a fluid escaped under high pressure. The patient then developed auditory aphasia with jargon aphasia. The disease being on the left side, it was assumed that a temporosphenoidal abscess was present, or one that involved the temporal convolution. After lumbar puncture had been done the patient began to improve, and on the following day the asphasia entirely disappeared and the patient made a complete recovery. It was difficult to base a diagnosis upon electrical irritability of the facial nerve. With regard to the cerebellar syndrome he believed it must be exceedingly rare, so far as abscesses were concerned.

Dr. Emil Gruening said that brain abscesses had never been opened and drained through the tympanic cavity by otologists. But if it was necessary to open through the roof of the tympanic cavity to remove disease, and a focus of disease was then met with, of course it should be removed, and through this opening.

Dr M. Allen Starr believed in an arraignment of all surgeons in this country for being so remiss in their work in brain surgery, and for the lack of proper attention being paid to this special branch, an important branch of surgery. Advances along the line of brain surgery had been made largely by Kocher, by Horsley, and by Macewen; but very few men in this country had taken up this important work. Dr. Starr wished, by his remarks, to stimulate work, in order to get a better percentage of recoveries in this important field of surgery. An exploratory puncture should not be made, but a wide opening; as a result of opening widely he had never seen a case of cerebral hernia, especially where the flaps were made of bone and replaced in a proper manner. Cerebral hernia as a rule was the result of sepsis. The danger of irrigation in these cases of brain abscess was only present when it was attempted through a small opening without any free exit for the fluid pumped in. With regard to the radiograph in brain abscesses, personally he had had only two cases radiographed, and with absolutely negative results in both. He had had a number of brain tumors radiographed, but without any benefit whatever.

Dr. Blake of Boston closed the discussion.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, Held December 14, 1905.

SECTION ON PEDIATRICS.

Dr. L. E. LaFetra in the Chair.

Cranial Gummatous Syphilis in an Idiotic Child.—Dr. Sara Welt-Kakels presented a boy, two and a half years old. There was no history obtained that pointed to lues in the parents. The child had never suffered from snuffles or any skin eruption He had six brothers and sisters living and well. At the end of the second year he had a discharge from the ear which lasted but a short time. At the same time he developed an abscess in the neck which was incised and healed after a period of four weeks. The first tooth appeared when he was two years old. He could not stand alone and made no efforts at walking and did not appear to recognize his parents. He did not speak even single words. While generally good-natured he occasionally became very excitable and destroyed everything within his reach. His appetite was voracious and he put everything in his mouth he could get his hands on, even paper and feces. Some five months ago a swelling appeared above the right eye and two months later a similar one appeared in the left temporal region. They caused no pain, and neither of these tumors had materially changed although he had been under treatment for some months. The boy was fairly well nourished, weighed twenty-five pounds, with skin and visible mucosa normal, with superficial lymphatic nodes enlarged. The face was apathetic, with rather a stupid expression, and he did not react to loud noises. The pupils responded to light and there was a left sided nystagmus. There was a slight loss of hair on eyelids and eyebrows. The bridge of the nose was somewhat sunken and he dribbled from the mouth and his hard palate was arched. The teeth were all present, some being carious. There were adenoids in the nasopharynx. Above the right eye on the frontal bone was situated a tumor the size of a fifty-cent piece, shaped like a watch crystal and not painful on pressure. The overlying skin was not reddened or otherwise changed. The consistency over the center of the tumor was elastic and in some parts gave the sense of fluctuation, whilst the circumference presented a hard ridge, apparently due to a reactive hyperplastic inflammation. Another somewhat similar swelling of the same character was found over the left temporal region. Exploratory puncture of the larger tumor revealed a bloody fluid which showed under the microscope very minute tissue threads. Very careful examination of the fresh and stained specimen failed to show the presence of the spirochete pallida. Dr. Welt-Kakels said that cranial syphilis in early childhood was not uncommon. Most frequently the long bones of the body were affected. Such an experienced observer as Hochsinger reported to have seen but four cases of gummatous syphilis among 600 nurslings with hereditary lues.

A Sugar of Milk Graduate.—Dr. Roland Godfrey Freeman presented this instrument which gave a fairly accurate measurement for all practical purposes.

Open Safety-Pin Swallowed by an Infant Six Weeks Old and Successfully Passed by Bowel Six Days Later.—Dr. Hedges of Montclair, N. J., reported this case. (See page 389.)

Hydrocephalus and Rachitis: Their Treatment by Radiant Energy, with Report of Cases.—Dr. Margaret A. Cleaves read this paper. She said that an agent which was able to penetrate not only bony structures but internal organs, tuberculous lesions, brain tumors, that had a predilection for lymphoid structures as evidenced by increased pigmentation in the spleen, that produced disturbances of the cellular equilibrium of the blood, that was destructive to germ life, that could so impair the vitality of the lining membrane of the seminal tubules as to prevent the reproduction of spermatazoa, and that could atrophy the Graffian follicles, could with perfect reason be expected to penetrate the cranial bones and act upon the effusion of fluid into the ventricles, acting at the same time upon the lining membrane or endothelium which was often finely granular and somewhat thickened. In so doing there would also be a helpful stimulus imparted to the brain structure itself, tending to the promotion of nutritive changes. Two cases were then reported in detail. The first case was a typical congenital internal hydrocephalus. The second case was diagnosed by four physicians as one of primary hydrocephalus. In this case the rachitic element was recognized at the first visit and although the opinion given as to treatment was based upon the slight symptomatic improvement obtained in the first case, the exhibition of *x*-ray energy was in this second case considered of comparatively little importance as compared with that of all the energies of the electric arc, from the lowest to the highest frequencies of vibration. As a matter of fact 14 *x*-ray exposures were made, and 16 arc light treatments given. The *x*-ray exposures towards the last were more of a perfunctory nature and continued for their moral effect upon the parents, in order to hold the child until the influence of light energy not only absorption but fundamental nutritive changes had been fully established. So strongly did Dr. Cleaves believe in the absorptive power of radiant energy that given any pathological condition with effusion she would expect to secure absorption and establish normal circulatory conditions, increase the oxygenating power of the blood, secure tonicity of muscular structerues and healthful functions from the use of light alone. In conclusion she emphatically stated that the report was not presented with the thought that in variant energy was to be found a panacea for hydrocephalus and rachitis, but to call the attention of the profession to the results obtained in the two cases, that the way might be open to further investigation of the subject. Such measure of success as was to be obtained would depend upon the character of a given case, *i.e.* the extent and duration of the pathological change. Treatment should be instituted upon the first manifestation of disease, even immediately after birth, but it should be administered with the full knowledge of the physics, physiological action and therapeutic technique of radiant energy, superimposed upon a knowledge of the pathology underlying the condition. It was well worth a trial. Because given conditions have always been regarded as in-

curable, was no reason that the profession should continue to so regard them. By radiant energy must be understood not only the *x*-ray, but all the energies of the spectrum of the electric arc.

Dr. Leslie Meacham said that he had seen the first patient at the end of the first week of treatment and he did not take much interest in it because he did not believe that anything could be done for the patient. When first observed there was no spontaneity and the patient appeared in a state bordering on coma; there was no movement unless the patient was aroused, and considerable stimulus was required to do this. The influence of the treatment seemed like the creation of a soul in the child, and after six weeks' observation the child was apparently normal, so far as intelligence was concerned.

Dr. Lewis Gregory Cole said that he had not seen the child when it first came under observation, but that when he did see it, the patient acted like a normal one.

Dr. Matthias Nicoll, Jr., said that there were not sufficient evidences of hydrocephalus in the second case reported and, in his opinion, it was not impossible that this was simply a case of rickets. While he had no doubt that the light treatment did have some effect upon the child's condition, one should remember that certain adjuvants as good food and good care aided greatly.

Dr. L. E. LaFetra said that the second case seemed to be to him one of rickets, pure and simple, and he believed that this case improved more rapidly than most cases did, and it was rational to believe that the light treatment was of additional value in the treatment of such cases.

Dr. Cleaves, closing the discussion, said that she could take a woman with an effusion in the pleural cavity so great as to produce dyspnea, with the heart pushed to one side, with the tappings showing evidences of new growth, etc., and could relieve her of her dyspnea from the time of the first treatment and cause the fluid to disappear; therefore one should be willing to believe that the fluid in the cerebral ventricles could be absorbed by the use of the light. She emphasized the importance of using this treatment so soon as the first manifestations of the disease presented themselves.

Gonococcus Vaginitis in Little Girls—Report of the Treatment and Results Obtained in a Series of Cases.—Dr. W. D. Trentwith presented this paper. He said that he had made note only of those cases which he had been able to follow to the end, so that results might be definite. In this series of twelve cases over 50 per cent. were infected indirectly by the father. That is, the mother had been troubled after her marriage with leucorrhea and on inquiry it was found had at some time or other had gonorrhea. Several cases which were infected by the sister ought also to be classed as indirectly infected by the father. One case had a discharge shortly after returning from a day nursery. The treatment was as follows: A soft rubber catheter, not larger than a No. 15 Fr. and a fountain syringe bag was provided. By means of a medicine dropper, connection was effected between the tubing of the fountain syringe and the catheter. The bag was filled with warm solution of potassium permanganate of the appropriate strength of 1-4000, then elevated three feet or more above the level of the bullocks, the child reclining on a duche pan, with the thighs flexed and abducted to the full extent. The catheter, lubricated with chondrus jelly or glycerin, was introduced into the vagina, and the full amount of solution allowed to flow. This was done two or three times daily, according to the severity of the case. A solution of potassium permanganate of the strength of 1-100 was prescribed; ʒvi to oij of water, which gave a solution of the approximate strength of 1-4000, and lent itself easily to any desired change in the strength. After the discharge became slight in amount and mucopurulent in character, the potassium permanganate was stopped and douches of equal parts of zinc sulphate and alum, ʒt to ot were given morning and evening. At each visit of the patient to the clinic, the same treatment was carried out. This was done not so much for the good that it did the child, as for its moral effect upon the mother. These cases were often long in getting well, because the mother neglected the treatment and must be impressed with its importance. When the discharge became slight and the child was using the zinc and alum douches at home, the physician used a solution of silver nitrate in strengths of 1-2000, 1-1000, 1-500, 1,250, 1-125 ʒi-ʒss were injected into the vagina. This usually completed the cure. The urethra became involved in only two cases of this series. By the application of a 10 per cent. solution of silver nitrate directly to the inflamed urethra the symptoms were relieved and the condition cured. The bowels were of course kept active and improper food prohibited. The mothers were instructed to keep the external genitals very clean by frequent washings with castile soap and dustings with talcum powder or boracic acid. The child should wear a napkin of bleached gauze, which could be thrown away. The mother was always informed as to the infectious character of the disease. The average length of treatment in the whole series of cases was four and a half months. Excluding two intractible cases the average time required was three and a half months. In the cases of primary infection in which treatment was begun under two weeks, the average length of time to obtain a cure was only seven weeks. He said that he had yet to see a case of vaginitis in which the catheter could not be passed without damage of any kind to the parts, provided gentleness was used and attempts to introduce it further were not persisted in after it met with obstruction in the vagina. The mother should be instructed as to the use of the catheter and should be made to pass it once or twice in the presence of the physician. It was not impossible that a neglected case of gonococcus vaginitis could go to womanhood, marry, and be the cause of gonorrhoea in her husband. In conclusion he emphasized the following points: 1. The great need for early diagnosis and treatment. 2. The necessity for frequent douching with large quantities of solution. 3. The non-use of absorbent cotton as a dressing for the parts. 4. The need for care and gentleness in the treatment. 5. That a case should not be considered as cured, until, not only the discharge had stopped, but it was no longer possible to find the gonococcus in the vaginal secretions microscopically. 6. The need of impressing the mother with the serious nature of the disease, and the necessity for treatment, until the gonococci had entirely disappeared. 7. The greater dissemination of knowledge among the men and women, who suffer from gonorrhea, as to its infectiousness to others, and its power to do, at times, great harm at a period remote from the time of primary infection, when the disease remained uncured. 8. The great necessity for care in keeping cases of gonococcus vaginitis out of the day nurseries and babies' hospitals because of the epidemic character which it assumed among the inmates.

Dr. Sara Welt-Kakels believed that most girls contrated gonococcus vaginitis from their mothers. Frequently women would come to the dispensary because the child was unable to walk; upon careful inquiry it would be learned that the child had been in the hospital with a specific vaginitis and had been sent home without the mother being informed as to the trouble, thus exposing other children in the family. She believed that Dr. Trenwith had been fortunate in effecting such quick cures. Often negative results were obtained with smears when positive results would be had by cultural methods. She used the same treatment as Dr. Trenwith, but the silver was used in stronger solutions and by means of a fountain syringe. The mother was always told the nature of the disease and instructed regarding proper disinfection of hands.

Dr. Henry Heiman said that this disease was one that was not easy to cure, and lasted not only seven weeks but sometimes even seven years. He preferred using Ultzman's posterior urethral syringe and had never seen any harm done by its use. He also used stronger solutions,

1 per cent. for the first week, used every day; 2 per cent. for the second week, used every second day; 3 per cent. for the third week, used every third day, etc., until the discharged ceased. He had found epidemic vaginitis in nearly every hospital in New York City. The only way to stamp out the disease in institutions was by adopting a rigid quarantine, such as would be adopted for diphtheria or scarlet fever.

Dr. G. R. Pisek believed that better results were to be obtained by packing the vagina than by the use of douches or irrigations.

Dr. G. D. Scott believed in the use of stronger solutions of argyrol or protargol in the treatment of gonorrheal vaginitis.

Dr. L. E. LaFetra said that at least nine-tenths of the cases of vaginitis seen in children were gonorrheal.

Dr. Trenwith, closing the discussion, said he did not claim any originality for this method of treatment. There was too much laxity among the people in the care of their hands after attending these cases.

Election of Officers.—*President,* Dr. Matthias Nicoll, Jr.; *Secretary,* Dr. John Howland.

MEDICAL ASSOCIATION OF THE GREATER CITY OF NEW YORK.

Stated Meeting, January 8, 1906.

The President, Dr. Thomas E. Satterthwaite, in the Chair.

Election of Officers.—The following officers were re-elected for the ensuing year: *President,* Dr. Thomas E. Satterthwaite; *Vice-President,* Dr. Ransford E. Van Gieson, of the Borough of Brooklyn; *Recording Secretary,* Dr. P. Brynberg Porter; *Chairman for the Borough of Manhattan,* Dr. J. Blake White; *Member of the Executive Council,* Dr. Reynold Webb Wilcox.

Presidential Address.—The President, Dr. Satterthwaite, in a brief opening address, reviewed the excellent scientific work done by the Association during the past year, and expressed the hope that the membership list of the Association, which was now 653, would be largely increased during his present term of office.

Symposium on Diseases of the Upper Air Passages.

1. Recent Advances in Diseases of the Upper Air Passages.—Dr. Wolff Freudenthal read this paper, in which he reviewed briefly the progress made by science in this special field during the past year or two. In the field of etiological research he said that much of importance had been published in recent years, and we now knew that several parts of the upper air tract were the portals for the entrance of infectious organisms. Tuberculosis and rheumatism were mentioned in this connection. Too much stress, however, had been laid upon the established fact that the faucial tonsils were found to be often involved in those two diseases, from which it was concluded that they constituted the main portals for many infectious microbes. Dr. Freudenthal said that he was not opposed to the removal of diseased tonsils, whether they were hypertrophied or not, but he could not agree with Gürich's claim ("die tonsillare Lokaltherapie des Gelenkrheumatismus"), made at the last Congress of Internal Medicine, held at Wiesbaden, in 1905, that the tonsils were the main portals of any infection, and required removal under all circumstances. The tonsils formed only one part of the great mass of adenoid tissue called Waldeyer's ring, and this entire area was apt to be the point of entrance for many germs, especially in its upper portion in the nasopharynx, where the well-known adenoid growths occurred. The speaker said that many years ago he presented the proof of his theory that the upper portion of this ring very often formed the portal for the primary infection in tuberculosis, and he thought this was equally true of other infectious diseases. More recently, his attention had been directed to the lingual tonsil, and he was surprised to find many enlarged lingual tonsils in tuberculous patients in his service at the Montefiore Home and the Bedford Sanatorium for Consumptives. Whether it was the cough that caused this glandular tissue to enlarge, or whether it was the manifestation of a primary infection, or of a secondary one extending from above, could not now be decided. There was a large field for future fruitful investigations in this direction. Dr. Freudenthal said that no one could deny the great progress that had been made of late in the treatment of tuberculous infections of the upper air tract, and it was not too much to assert that the great majority of the patients could be relieved of their dysphagia and the irritating cough that had its origin in some part of the upper air tract. Marked progress had also been made in relieving deformities of the face by the injection of paraffin. Unfortunately, however, the procedure was not without danger, as several cases had been reported in which total blindness of one eye resulted after such injection, caused by particles of paraffin getting into the arteria centralis retinæ, and acting as an embolus. Among other recent advances in the treatment of diseases of the upper air passages, Dr. Freudenthal mentioned tuberculin and the various rays, including the actinic, the Roentgen, the high-frequency current, and the rays emanating from radium. For the treatment of dry and atrophic catarrh of the nose, he mentioned the new suction method of Spiess of Frankfort. For the endoscopic examination of the maxillary sinus, Alfred Hirschmann of Berlin had devised several novel and useful instruments. He also called attention to the submucous resection of deflected nasal septa and spurs, especially after the method of Ballenger, and referred to the control of nasal hemorrhage by the subcutaneous use of adrenal extract, the injections to be made at the nearest accessible point to the bleeding area, as practised by Dr. H. J. Mulford of Buffalo. In conclusion, he referred to Dawbarn's method of constricting the upper part of the thighs or arms in order to decrease the loss of blood in the course of any severe operation where much hemorrhage was feared.

2. Hypertrophy of the Pharyngeal Tonsil; Lymphoid Hypertrophy at the Pharyngeal Vault, or "Adenoids."—Dr. Frank C. Raynor of Brooklyn stated that this condition, which was first discovered by Czermak, in 1860, and was brought practically before the profession by Wilhelm Meyer of Copenhagen, in 1870, attracted comparatively little attention in this country until the middle eighties. Since that time the subject had received a great deal of notice in medical literature. In some respects, the popular term, "adenoid" (glandlike), was unfortunate, for the lesion was not, anatomically, a true secreting gland, but was composed of lymph cells and connective tissue arranged in the form of a lymph node, which was covered by columnar epithelium, irregularly ciliated. These nodes were arranged in masses which varied greatly in size, shape, consistency, and attachment to the nasopharynx. They were not, strictly speaking, new growths, being only an overgrowth of the normal histological elements of the mucous membrane lining this cavity. The disease was principally one of childhood, but might be encountered at any age, for while the lymphatic tissue normally present usually atrophied about puberty, hypertrophied tissue remained indefinitely. The diagnosis could usually be made from the symptoms alone, and might be confirmed by examination of the nasopharynx with the rhinoscopic mirror, or, in doubtful cases, by a digital exploration of that cavity. When the faucial tonsils were hypertrophied in children, adenoids could be safely assumed in nine cases out of ten. In the treatment of adenoids but little could be accomplished medicinally when the disease was at all advanced. In mild cases, particularly in very young children, he had sometimes obtained relief by the instillation of liquid petrolatum, containing two grains of menthol and ten minims of eucalyptol to the ounce. This was best applied by dropping, with the ordinary medicine dropper, two or three

minims into each nostril, morning and night, the child lying on the back while the application was made, and kept in that position until the medicament had time to reach the nasopharynx. Speaking generally, the use of sedative and astringent applications in order to relieve symptoms was to be discouraged. The caustic applications recommended by some authorities, the speaker said he had never employed, and the thought the risk attending their use far outweighed any possible benefit that might be derived from them. After a brief review of the various surgical methods of treatment, Dr. Raynor said that the instrument he most favored was a modified Gottstein curette, with which, together with a specially-bent curette for the posterior wall, he believed he was able to clean out a nasopharynx quicker than in any other way. He operated with the patient lying on the right side, which was convenient for the operator and best for the patient when under an anesthetic, which he almost always employed, ether being the agent used. After the operation, the patient was kept in bed for a day or two, and confined to the house for a few days more. For the first twenty-four hours the patient should sleep on the side, in order that any secondary bleeding might be readily discovered. No local after-treatment was necessary. When adenoids and hypertrophied tonsils were both present, a very common condition, he usually attacked both at the same time, removing the tonsils first. The result of the operation for adenoids was usually highly satisfactory, and the improvement that took place in some children when freed from this disability bordered on the marvelous. In discussing the treatment of hypertrophy of the faucial tonsils, Dr. Raynor said he thought the only rational method of dealing with this condition was by a total extirpation of the diseased mass under general anesthesia. In other words, it should be treated as one would treat any other diseased lymphatic gland on which an operation was deemed necessary. This could not be accomplished by a tonsillotomy, as ordinarily performed, excepting in unusually favorable cases. Becoming dissatisfied with the results obtained from the use of the guillotine some years ago, the speaker said he began dissecting out the tonsils, gradually modifying his technique to the operation described by his colleague, Dr. W. H. Steers, in an article published in the Medical Record October 3, 1903, to which he referred for fuller details.

3. The Accessory Sinuses.—Dr. Hubert Arrowsmith of Brooklyn read a paper with this title, in which he briefly discussed the various diseases of the accessory sinuses, and methods of treatment.

4. Indications for Treatment in Acute Diseases of the Accessory Sinuses.—Dr. Henry L. Swain of New Haven, Conn., discussed this phase of the subject. He stated that ever since the invasion of this country by the first great epidemic of la grippe the number of cases of accessory sinus disease had largely increased, and many of the acute cases had developed into chronic empyemas, which frequently remained unrecognized, being called merely cases of chronic catarrh. The systematic transillumination of all cases of severe coryza would often, on the third or fourth day, show slight thickening of the shadow of one or all the sinuses. These subsequently cleared up in many cases, and were, without doubt, as he had been able to prove on several occasions in dealing with the maxillary and the frontal sinus, due to an accumulation of serum, which, when it did not become infected, was evacuated, and the patient was cured. From this it could be deduced that if the nose was kept clean of infected material, infection of the accessory sinuses might be avoided, and the first prophylactic indication, therefore, was not to neglect cases of mucopurulent catarrh. With every bad "cold" there was always a stuffy feeling about the head, pressure in the upper part of the nose, and, perhaps, headache, and this, in cases of frontal sinusitis, merged into a browache. The patient became conscious, sometimes suddenly, but more often gradually, that most of the ache was confined to the brow over one or both eyes, with a feeling of weight and pressure, and tenderness of that portion of the brow nearest the nose. When, with this, there was one-sided mucopurulent discharge, or when the discharge was freer on one side than the other, usually with more flow between the daily hours of nine and three o'clock, the symptoms pointed strongly to frontal sinus involvement. Transillumination was of distinct value in confirming the diagnosis. Or, by spraying out the nose with cocaine and suprarenal solutions, and then cleansing it, first by blowing and then by wiping out the middle meatus, one could frequently readily detect a stream of pus flowing down from the anterior part of the middle meatus toward the back of the nose, giving the assurance that the discharge came from the frontal sinus region. Usually, also, the anterior end of the middle turbinate bone was swollen and club-shaped. In later cases one saw almost always granulation tissue at the anterior end of the middle turbinate bone, blocking the opening of the infundibulum, which was just above and behind the point of junction of the middle turbinate with the side wall of the nose. The introduction of a probe into the lower part of the infundibulum, and producing a gentle backward and forward motion would frequently result in pumping down the fluid so directly from the frontal sinus that an absolute diagnosis was immediately established. The first indication for treatment was to relieve the pain by establishing good drainage. After reducing the swelling by the use of mild cocaine and suprarenal solutions, the introduction of a probe into the frontal sinus through the natural passages was often perfectly easy, and usually painless. The probe, of a proper curve, should, if possible, be passed into the frontal sinus cavity itself. When this proved impossible, after repeated efforts by competent hands, owing to blocking of the outlet, it was perfectly proper to remove the anterior end of the middle turbinate in order to accomplish a satisfactory entrance and establish free drainage from the frontal sinus. Dr. Swain then briefly reviewed the symptoms and indications for treatment in acute diseases of the other accessory sinuses, including the anterior and posterior ethmoid cells, the sphenoid, and the antrum of Highmore. In all these cases the methods of treatment were essentially similar to those described for the frontal sinus.

Dr. Satterthwaite said that Dr. Charles H. Knight, who was to have read a paper upon the serum treatment of hay fever (see page 379), would be unable to be present on account of illness. In order that this phase of the subject might not be left out of the discussion, Dr. Satterthwaite said that he would like to give his personal experience with Dunbar's serum. For a number of years he had been a sufferer from hay fever, the attack usually coming on the second of July. Last summer he was persuaded to give Dunbar's pollantin a trial, and he did so, introducing it both into the nostril and the eyes, and his attack of hay fever, instead of lasting twenty-eight days, as it had hitherto done, was over in twelve days. He attributed the curtailment of the attack either to the pollantin or to the fact that he had spent a good deal of his time in July in playing golf.

Dr. Joseph W. Gleitsmann said that while his personal experience with the serum treatment of hay fever was limited, he had come to the conclusion, from his reading and observation, that the same serum would not answer in all cases, and that we needed a different serum here from that employed abroad. The speaker said that the statement made by Dr. Freudenthal that tonsillitis could no longer be regarded as a local disease, and that rheumatism was a very potent factor in its production, was now recognized by all. Especially in the type of tonsillitis in which the follicles and lacunæ were invaded, local remedies alone were not sufficient. Dr. Gleitsmann said he was glad to hear Dr. Freudenthal speak of primary tubercular infection of the lingual tonsils. Personally, he had observed a few such cases, and he had in mind one particular case in which the primary infection of the tonsil could be demonstrated beyond the shadow of a doubt. The patient was a woman, in whom the disease began in the lingual

tonsil and extended to the pharynx. The disease was very extensive, and drastic measures were adopted to eradicate it. The patient was entirely cured, and fourteen years had now elapsed, without any signs of a recurrence. She had never had any symptoms of pulmonary tuberculosis. Dr. Gleitsmann said that in selected cases of tuberculosis he was still in favor, as he had been for a number of years, of injections of a good preparation of tuberculin, either the older preparation of Koch, or, preferably, the preparation of Dr. Carl von Ruck of Asheville, N. C. The speaker agreed with Dr. Raynor that the thorough removal of adenoids necessitated the use of an anesthetic, and he believed that the operation could best be done in the upright position.

Dr. Bryan De Forest Sheedy said he had found it quite impossible, in the majority of cases, to probe the frontal sinus, and he was not in agreement with what had been said in regard to the treatment of frontal sinusitis by the open, external operation. The matter of packing the sinus externally and maintaining an opening there was more serious than it was usually regarded to be, and the marked deformity it might give rise to should not be overlooked. In regard to the examination by transillumination, the speaker said he had found the method unsatisfactory and wholly unreliable, as we were apt to be misled by the varying thickness of the normal bone and tissues in different individuals. Personally, he had given up the use of the light altogether, excepting as an aid to other means of diagnosis. In adrenal and cocaine solutions we possessed two valuable remedies for the reduction of swelling of the nasal tissues, and in the early stages of frontal sinus disease they would often give the patient wonderful relief. The results of treatment obtained by this conservative method were much better than they had been heretofore, and the number of cases that progressed into the chronic stage would doubtless be largely decreased thereby. Dr. Sheedy said he did not regard the existence of even advanced pulmonary tuberculosis as an indication for the induction of premature labor, as had been advised by some. He considered the removal of adenoids without an anesthetic as cruel, even in young children, and favored the practice in vogue in the London City Hospital, where it was obligatory upon the surgeon to give an anesthetic in those cases, although there they preferred chloroform to ether. A small amount of ether would spare the child much pain, and render the operator's work easier and more thorough.

Dr. H. Beaman Douglass said he agreed with Dr. Sheedy in regard to the unreliability of transillumination in the recognition of frontal sinus disease; in his clinic they had discarded the method entirely. In regard to probing the frontal sinus, he did not claim that the probe had entered the sinus until its presence there could be verified by the *x*-ray. While the introduction of cocaine had proved a great advance in the recognition and treatment of diseases of the upper air passages, it had also revealed other problems that were still unsolved, and where patients a decade ago complained of unrelieved obstruction, they now demanded to be relieved of the mucoid or mucopurulent discharges from which so many of them suffered.

Dr. Lewis A. Coffin said that in the removal of adenoids or tonsils he did not think it mattered much what instrument the operator preferred, or what the position of the patient might be; the chief point was to remove the offending growths, and remove them thoroughly. In the removal of adenoids he usually preferred to do the operation under chloroform anesthesia. While transillumination could not be solely relied upon in the diagnosis of frontal sinus disease, it was a valuable accessory in the recognition of that condition. Dr. Coffin said he had failed many times to introduce a probe into the frontal sinus, and in those cases where he succeeded he always liked to verify its presence there by taking a radiograph with the probe in position.

The discussion was continued by Drs. Lee M. Hurd and Robert C. Myles and closed by Dr. Swain.

Successful Surgical Intervention in a Case of Accidental Scalping.—Colle describes this case. The scalp, which had been torn from the head, was still adherent in the occipital region. The periosteum and the skull remained intact. The scalp was shaved and the two surfaces were then disinfected. The scalp was sutured in its entire circumference. The operation was performed without chloroform. It was entirely successful, for in eighteen days the wound was cicatrized. The patient, who at the time of the accident was in the eighth month of pregnancy, gave birth to a child at term one month later.—*La Presse Médicale.*

Health Reports.—The following cases of smallpox, yellow fever, cholera, and plague, have been reported to the Surgeon General, Public Health and Marine Hospital Service for the week ending March 3, 1906.

THE BORDER LINE IN MEDICINE AND SURGERY.*

By E. G. JANEWAY, M.D.,

NEW YORK.

Not a few cases of disease occupy that debatable ground which may be called the border line of medicine and surgery. No more fitting subject suggested itself to me for presentation this evening, feeling sure that it would lead to a profitable interchange of views, should I be fortunate enough to bring out certain salient features for discussion.

In our city the physician and surgeon can consult together, and though the former has not the difficulty of many a rural practitioner, who has to debate with himself, he is not freed from the responsibility of helping to reach the decision whether a given case be subjected to surgical or medical treatment; whether, in fact, the former is best adapted to relieve the patient from the malady which is undermining health or threatening life. At the present time asepsis enables the surgeon to do successfully much that could not be undertaken in the earlier years of my medical career. Pyemia, septicemia, and kindred complaints have become such rarities in well-conducted institutions, and as attendants on the operations performed by careful surgeons, that the physician is at ease in his mind on that score, and can with clear conscience, and with great hope of success, recommend surgical exploration and operation. It is worth while, however, to draw attention to certain conditions which may have a deterring influence even in cases of serious need.

Operation may be refused, owing to the patient's mental attitude, self-existing, or brought about by the intervention of relatives or friends. It should be our aim, then, to study the causes which underlie such a state of mind in order to obviate and overcome its dangerous effect. One of the most difficult objections to meet is that founded on a limited experience. The contention is that a relative or friend resorted to surgery with unsatisfactory or fatal result, whereas the statement had been made by the surgeon that all would go well. Herein lies the unfortunate part of the subject; and it is well for surgeons to realize that unfulfilled predictions, and a too great optimism in a given case may be the means of loss of life, or continued invalidism in another. It may mean, as in two cases recently observed, either that the undertaker is preferred to the surgeon, or that ill-health is endured. Surgeons at times take too roseate a view, when conservatism and more moderate statements would have left a better effect upon the minds of the family and friends.

Certain operations, moreover, are at times performed, which amount practically to taking surgical chance in hopeless diseases. It is the position of a drowning man catching at a straw. If, in addition, a large fee is charged, the laity are apt to take a serious view of the matter, and surgery is brought into more or less of disrepute. Operations, too, which may be viewed in the light of curiosity performances, are likely to generate the same effect. These may be denominated such as are undertaken where there is no reasonable hope of cure by surgical intervention, in order to more fully, if possible, make out the exact state of affairs. The mode of reasoning adopted in such cases has much plausibility. It is argued if the disease be the worst supposed to exist, then this of itself will eventually prove fatal, and, in consequence, lest perchance some other condition may be discovered which might be relieved, an operation is to be recommended.

In dealing with the border line cases it is in my judgment advisable to obtain as nearly as possible an accurate diagnosis before resorting to surgery. In this we find more or less diverging views, not alone between physicians and surgeons, but somewhat between each of these classes. It is easier at times to cut the Gordian knot than to attempt a solution of the difficulty by slower methods. In other words, careful attempts, employing all available means, should be made to form a correct diagnosis before resorting to the knife, except in cases of great urgency. It is customary amongst certain physicians and surgeons to believe that to make the diagnosis as the result of surgery is the better method. The difficulty, however, lies in the fact that by this course an unnecessary operation may be performed, or that the operation having been begun, may need to be repeated in another direction, because the incision has disclosed that the organ or viscus supposed to be affected is free from disease, and has brought out the fact that another organ is the site of trouble. Examples of this are not difficult to find: for illustration, allusion may be made to renal calculus, leading to appendectomy; gall-bladder disease mistaken for appendicitis, or renal trouble, and vice versa. Owing to reflected pain, pneumonia or pleurisy may simulate appendicitis or an acute abdominal disease needing operative procedure.

The rule, which should be formulated in the physician's mind, is that no operation should be performed without a careful examination of the body by a person competent to form an intelligent opinion. I have known surgeons on several occasions to refuse to operate, because they had found conditions in organs overlooked by the physician who had called for their services. Here allusion may best be made to the need of a careful cross-examination of the patient as well as an investigation of any conditions present on the body in order to determine if any luetic infection has existed which might have a bearing on diagnosis, and lead to an attempt to produce a cure by antiluetic measures. It

*Read before the Practitioners' Society of New York, February 9, 1906.

is certainly disappointing to cut into a morbid growth, removing a portion for the microscope, or to remove the growth, and then ascertain that it is of a specific nature which yields to specific treatment later administered. It would be wise to use this means first, and employ the knife if failure occurred. The objection is that at times an apparently beneficial effect is produced at first by the employment of these measures, where the course of the case with operation or the result of a post-mortem examination proved the growth not to be of a specific character. Such objection does not, in my opinion, have as tenable ground for insisting on operation first, as that above made for the reverse method of procedure.

Again, a thorough inquiry should be made as to medicines, which have been taken or administered. This holds good more especially where the debatable point is about nervous disease,—unconsciousness, or lethargy, for example, where otitis media had existed, being taken to indicate the possibility of meningitis or brain abscess. Past experience brings to my mind the following notable example in this direction, bromism, from large doses, of a bromide preparation in a susceptible person, being the explaining cause of somnolence with which a man who had suffered from otitis was brought to New York to be operated on for brain abscess.

But this inquiry is not needed in brain or ear cases alone; it may be of value in abdominal cases as well. Here it is necessary to consider medicines of an iritating nature, those of a sedative character, and especially such an astringent as lead. Moreover the possibility of accidental taking of a poison, or self-administration of the same with suicidal intent, is to be considered. It is at times stated that lead medicinally administered will not produce toxic effect. This statement is not correct, as observation of cases to which I have been called, and of one to whom I had given lead for loose bowels, has proved to my satisfaction. It should be remembered, also, that corrosive sublimate may not produce salivation, though taken by the mouth.

Not infrequently the physician may object to a second operation being performed upon a patient exhausted by diseased conditions and an operation for their relief—as after an operation for the overcoming of pelvic conditions, nephropexy is performed upon both sides. In case of a bad outcome from any of such operative procedures, not alone the surgery of such given case is brought into discredit, but, as I have already stated, surgery in general will receive from inconsiderate people readily, and from those also who reflect, a bad reputation. It is, however, to be borne in mind that if the patient has been informed that he or she may require two operations, and has expressed a positive wish for having everything attended to on one occasion, then the surgeon is so far absolved, as he has conscientiously believed that the patient was in a condition to have the extra operation.

Another question which may arise in this border land, relates to the assertion which is at times made, that if an operation is performed, then the state of the viscera, etc., having been observed, we are sure of the internal conditions. There exist enough cases which show that growths which an attentive inspection seemed to prove to have been of a malignant nature can disappear. This has occurred with palpable tumors supposed hence to be malignant and inoperable. Such cases baffle both sight and touch, and are in all probability to be considered as inflammatory masses. They also teach us that the disappearance of palpable masses in the abdomen must not be inevitably ascribed to medication used, or to light therapy where that has been employed.

Now that I have spoken rather fully as regards the surgical side, let us turn to the medical and reflect for awhile about the surgeon's complaint of the physician. Dr. McBurney read a paper at one of our meetings lamenting the late stage at which the surgeon, in not a few instances of malignant growth, was called upon to operate. It was then pointed out that the delay was frequently due to the patient having failed to appreciate the nature of the malady, or that any malady existed which required active measures. This was more especially regarding external growths, as of the breast. If at times physicians delay too long in these cases where sight and touch help in the ability to make out morbid growths, it is much more the case when we consider internal processes—cancer of the stomach, bowels, etc. At that meeting it was regretted, if my memory is correct, by physicians, that the necessary uncertainty too often delayed the question of operative intervention beyond that point where a radical operation could result in a cure. Of course this will only excuse physicians who make a careful study of each case, and where uncertainty is due to irregularity in the development of the phenomena of disease. Time is a great factor in the establishment of a diagnosis, and what was uncertain to a medical predecessor may, by the natural development, have become clear to the one who succeeds. This occurs so frequently that I am sure each can bring before his mental vision sufficient illustrations.

Physicians, in considering the etiology of disease —especially, though not exclusively, of the abdomen—need to bear in mind the possible influence of previous operation in the production of the pheomena of which the patient complains. Two recent cases have particularly emphasized this to me —one a case of obstinate vomiting occurring nine months after ventral fixation, cured by operation by a fellow member, Dr. W. T. Bull. Another, also of ventral fixation, with partial ovariotomy, having bowel symptoms with mucous colitis since.

Many as are the important considerations which demand attention both of the physician and surgeon, a few may be considered this evening because of their bearing on the propriety of an operation. Among the first in the mind of the laity is the question of heart strength. Not a few people fear that the heart will fail under anesthesia or subsequent thereto. Hence a careful study of its state is a help to the patient. Compensated valvular disease is no objection to a carefully performed operation, and it has at times been a surprise to me to notice how well patients with organic heart disease have stood operative procedure. The same has been true as regards hearts which were symptomatically weak, but which were able to carry patients not only through the period of anesthesia and operation, but also through that of convalescence.

The records of operations for empyema on persons who for some time may have had hearts so rapid and feeble that so-called cardiac stimulants were constantly employed to overcome the depressing influence of septic absorption will prove this contention. The same has been observed as regards weak hearts in operation for bowel obstruction. I have elsewhere alluded to a remarkable case in which a fellow surgical member and I were each rather fearful about the outcome for a lady somewhat advanced in years, who had had symptoms of cardiac weakness, and yet stood a rather long opera-

tion involving not only the section of a band compressing the lower part of the ileum, but also a resection of the injured portion of the bowel, making a complete recovery. The same favorable statements could be made by our gynecological members about certain necessary operations in their department. Yet this must be tempered by my previous allusions to inoperable cases.

No better place can be found for mention of the great advantage accruing to the patient by the employment of a thoroughly competent anesthetist who devotes himself to the study and practise of anesthesia. I have on several occasions been able to persuade people to have a necessary operation done by assuring them that a person of that class would have charge of the administration of the anesthetic. Most of us can go back to the time when the person who administered the ether or chloroform was craning his neck to get a view of the surgeon's work instead of minding his own business, with the not infrequent consequence which comes to people who attempt two things at the same time, whether it be riding two horses, mounting two stools, or attempting to study an operation and give an anesthetic.

In cases of jaundice of any considerable duration there is danger of hemorrhage leading to a fatal result after operation. Hence the physician has a double duty in so much as he should bear this in mind when treating obstructive jaundice, and decide at as early a date as possible in regard to the probable need of surgical intervention. If the necessity should be decided to exist, then a study of the blood coagulation time should be made. Formerly five out of six succeeding cases operated on because of obstructive jaundice by my advice, and by the foremost surgeons of this city ended fatally within a week after the operation from hemorrhage. Such a result was very discouraging, and for some time I had a strong mental disinclination to overcome before advising deeply jaundiced people to submit to operation. That it still exists the above remarks prove, but I have been impressed with the necessity of early operation in suitable cases.

More instructive have been the operations upon the kidney for decapsulation. They have tended to show the ability of patients with nephritis to resist, not only anesthesia, but also the operation. At one time physicians feared anesthesia if albumen and casts were present. Instead of this determination, it is important to ascertain the sufficiency of the kidneys—a little albumen and a few casts may exist for years after they were the cause of fear as regards the patient's ability to take ether and to overcome surgical procedures. In recent times the very careful studies made about the conditions of each kidney have been of marked benefit where disease of one kidney may demand operative relief. It may interest you to know that I have at times been consulted by the family physician in regard to the propriety of decapsulation of the kidneys, recommended to their patient by enthusiasts on no stronger basis than that the urine had a slight amount of albumin and a few casts.

The physician has not infrequently to consider carefully whether the degree of anemia present is such that he should not advise surgical interference until an attempt, where circumstances admit, had been made to bring about a better blood state. In each case of severe anemia it is wise to attempt this as above said, circumstances permitting.

The question arises whether it is better to have an absolute limit below which no severe operation would be performed. This limit has been set at 30 per cent. of hemoglobin (Mickulicz). Yet, as it is claimed that operations of some severity have been successful where the amount of hemoglobin has been below this, we can only reach the conclusion that other circumstances than the hemoglobin hold must at times be the determining influence. If there is an opportunity to improve the blood state where the hemoglobin is low, then prudence would caution physician and surgeon to postpone operative procedure.

The presence of diabetes in a person to be operated upon always produces a certain amount of fear as regards the outcome. Yet much will depend upon the type of the disease. Naturally, the rule should be that only operations of urgent necessity should be attempted upon those having the severer types. Trivial abrasions, such as the careless manicurist may produce on the toes, or which may follow a slight injury, have at times such serious outcome that a careful study should be made of any person having sugar in the urine who seeks surgical help.

The physician is obliged also, in view of certain published results, to face the question whether he shall immediately seek surgical aid in case of collapse due to shock from stomach perforation, etc. The surgeons have found that the old rule, to wait for operation until the shock has passed, has usually a bad result, or, rather, a worse outcome than the immediate performance of laparotomy with repair of damage.

At the close of the paper I may ask, are certain palliative operations of such value to the patient as to be inevitably seriously recommended? Assumed that the primary disease cannot be removed and that death in time is inevitable, is it worth while to recommend such operations as the production of a gastric fistula in cancer of the esophagus?—or artificial anus in an inoperable cancer of the rectum not markedly obstructive? I must confess that I do not feel inclined to urge the patient to dubious palliation, and I believe that we can best take council with the family or near friend of the patient upon this subject, placing the matter candidly before them; and if they decide against attempts at surgical palliation, I do not consider that they have acted very unwisely. I have been led to these considerations by a patient who refused an operation for artificial anus, which I recommended, because he had witnessed the life of a friend who had one. Moreover, it has rarely been my lot to witness a more unsatisfactory existence than that of a patient in whom a gastric fistula had been made by my advice for cancer of the esophagus. But in any case where a doubt exists about a possible cure, as in certain bowel growths, or in such as a rational doubt may obtain as to the nature of a process, then I would advocate an operation.

Many other matters seemed to claim consideration—as age, the condition of the arteries, defective vitality, etc.—but it seems to me that I have introduced in a rather haphazard way sufficient subjects to be of interest to you, and such, more particularly, as I have found at times causing me rather anxious thoughts, when considering the best for a patient who occupied this borderland of surgery and medicine.

A Prejudiced Opinion.—The Canadian nurse is preferred in the United States to her sister worker of American birth. Physicians in all the great cities on the "other side" readily admit their preference for Canadians. When asked his reason for invariably telephoning "Send a Canadian," a New York doctor replied, "They have steady nerves and are more obedient."—*Canadian Magazine.*

FEVER IN TERTIARY SYPHILIS.

By DUDLEY N. CARPENTER, M.D.,
SURGEON U. S. NAVY.

THE *Lancet* for November 25, 1905, states that though it is well recognized that fever may occur in the secondary stage of syphilis, its occurrence in the tertiary stage is not so well known and may cause difficulty in diagnosis. It quotes the following case of Dr. A. Birt, reported in the *Montreal Medical Journal* for October:

"A man, aged forty years, who had chronic urethritis and stricture, for which he had undergone operation, complained of loss of flesh and strength. A painless enlargement of the liver had been detected by a genitourinary specialist. There was no history of alcoholism, syphilis, or malaria. The complexion was sallow and the temperature and urine were normal. The liver was moderately and the spleen a little enlarged. A tentative diagnosis of congestion or early cirrhosis of the liver was made. Under treatment the patient improved. Eight months later, when he was again seen, he had much changed for the worse. For two or three months his health had failed and he had lost weight and strength and had suffered from cough, night sweats, and pains in the lower part of the chest and right shoulder. The chest and sputum were repeatedly examined for tuberculosis with negative results. The patient was pale and sallow, but not jaundiced. The feces were scanty, dry, and pale. There was a constant evening rise of temperature to 100° or 101° Fahrenheit, a morning remission to subnormal and profuse night sweats with occasional slight chills. The liver was moderately enlarged and had a well-defined margin. It was very tender, and on deep respiration dragging pain was felt over it and radiated to the right shoulder and upper chest. The spleen was somewhat enlarged, palpable, and tender. Two months later light was thrown on the diagnosis by the detection of a small tender node at the costochondral junction. Only then did the patient admit that he had contracted syphilis eleven years previously. Under moderate doses of mercury and iodide of potassium astonishing improvement took place. After forty-five grains of the iodide had been taken the fever disappeared. The appetite promptly returned and the pains ceased. In six weeks he gained twenty-two pounds in weight and in seven weeks the liver, which measured six and three-quarters inches in the right nipple line, had receded to the costal margin and was no longer tender. Complete recovery ensued.

"When fever occurs in tertiary syphilis, night sweats, loss of weight, and pain in the chest often occur and the disease is liable to be mistaken for tuberculosis or malarial fever. In the *Transactions* of the Association of American Physicians for 1898 Janeway has reported six cases of syphilitic fever in which the patients were treated for tuberculosis. Syphilitic fever has also been mistaken for typhoid fever and for septicemia."

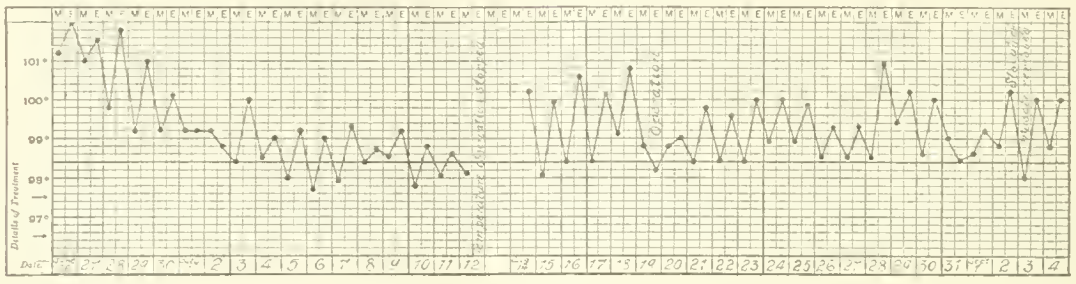

CHART 1.

This difficulty in diagnosis of fever in tertiary syphilis has recently been illustrated by two cases under treatment at the U. S. Naval Hospital, Puget Sound. It would seem, therefore, of interest to report these cases in some detail:

CASE I.—Male, aged twenty-four years, admitted June 26, 1905, with remittent fever, said to have originated at Panama, the first attack of fever having occurred while his ship was at that port. He was treated with quinine and arsenic for several weeks and was able to return to duty. The fever soon returned, however, and he was transferred to this hospital. Quinine had been given in large doses. Examination on entrance showed the patient to be emaciated and sallow. Family and past history negative (syphilis denied). Habits, good. Chest and abdomen apparently normal. Urine normal. Quinine was stopped at once and Fowler's solution with an iron tonic pill was given. Examination of the blood was made daily without finding the malaria plasmodium. The hemoglobin (Tallquist) was 95 per cent. There was no leucocytosis.

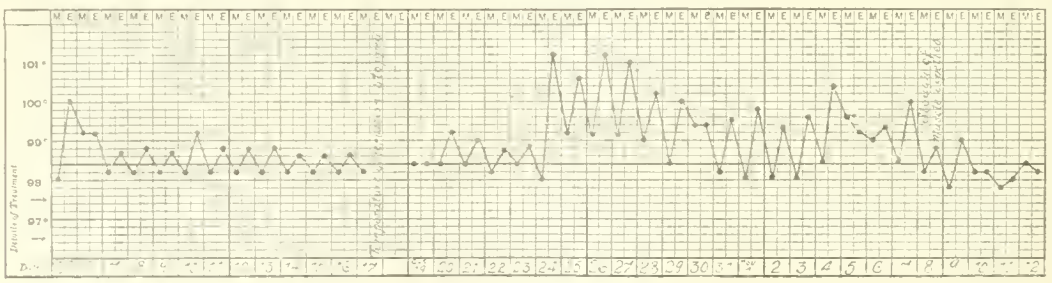

CHART 1, Continued.

On June 30 the patient had some cough, and as he had been sweating at night with occasional chills his sputum was examined for several days without finding the tubercle bacillus. On July 7 a slight swelling over the sternal notch was noticed

and he was accused again of having had syphilis, with admission on his part that he had had the disease four years ago, but believed himself cured owing to long-continued and careful treatment. The diagnosis was therefore changed and specific treatment instituted. He was given gradually increasing doses of protiodide of mercury in pill form, with ungt. hydrargyri externally over the swelling. In a few days there was a decided improvement in his appetite and strength and some gain in weight. He was allowed to get up from his bed and for a week the temperature was not taken. It was believed that the slight evening rise was due to syphilitic cachexia. The return of sweats, headache, and slight chills caused the temperature to be again determined on July 15. On July 28 there was a decided increase in the swelling extending from the sternal notch along the border of the right sternocleidomastoid muscle.

The protiodide pills at this time had to be discontinued, and potassium iodide was given. By August 12 there was a decided loss of flesh and strength, and for a week the swelling was carefully watched in view of operation. The protiodide pills were again cautiously used. It was finally decided to make an exploratory incision. Therefore on August 19 he was given chloroform, and an incision to the bone was made over the sternum, extending upward and exposing the lower part of the sternocleidomastoid muscle. A pocket of thin brown pus was found at the sternal attachment of the muscle, the base being formed by a small area of necrosis of the anterior surface of the sternum. Several necrotic fragments of bone were removed by the curette. The anterior border of the sternal portion of the muscle was necrotic and a small sinus extended beneath it for a distance of about three inches. All the affected muscle was removed and the sinus curetted. The upper part of the incision was sutured and an iodoform gauze drainage wick inserted through the lower opening of the incision. The patient felt much improved after the operation. There was a decided gain in strength and appetite.

Daily dressings of the wound continued, the bone being gradually covered by granulations. On August 29 the protiodide pills had to be again discontinued and the potassium iodide given alone. The sinus in the neck did not heal readily, and on September 2 a large piece of necrotic muscle was discharged. At this time the nasal bones showed signs of necrosis, although there had been a purulent nasopharyngeal catarrh for several weeks and necrosis was suspected. A small ulcer of the velum palati appeared on September 9.

The treatment was now changed to a fresh mixture of mercury and potassium iodide. Malt extract was given as a tonic. Local treatment of these ulcers by saline irrigation, Seiler's solution, H_2O_2, silver in solution or in solid stick, and powdered iodoform, all were faithfully used. There would be a partial healing and then a fresh area would become involved. During October, tonic pills and cod liver oil were given. Finally on October 18 there was so little improvement of these discharging ulcers and the open sinus in the neck that it was decided to omit the mercury and give the potassium iodide alone. Observation seemed to show that with the mixed treatment containing mercury whenever the dose was moderately increased the lesions became aggravated. The potassium iodide was rapidly pushed to 120 grains daily, and on November 8 another slough of muscle was discharged from the sinus. From this time on the sinus of the neck rapidly healed, the ulcer of the palate gradually closed, and the discharge from the nose ceased. The patient gained his former weight and strength, and finally on December 8 he was discharged from the service with no open lesions. There had been no fever for nearly two months. The usual "saddle nose" resulted from necrosis of the nasal bones and the right sternocleidomastoid muscle was reduced to a thin band.

Case II.—Male, aged twenty-seven years. This patient was admitted with the diagnosis of bronchitis chronica and suspected phthisis. There was a history of syphilis contracted eleven years ago, and it was stated that syphilitic treatment had been recently used. Examination on entrance, July 11, 1905, showed the patient to be emaciated and anemic. Examination of the heart, lungs, and abdomen gave negative results. Family and past history negative. He complained of slight dry cough and pain in the chest, with headache and sweats at night. There was no appetite and the bowels were costive. The cervical and submaxillary glands were enlarged and there was a marked pyrrhœa alveolaris of both jaws. The urine was normal. The blood contained no malarial plasmodia. The sputum was examined daily for several days without finding tubercle bacilli. Over the sternum, at the junction of the manubrium and gladiolus, there was a slight swelling, tender to the touch.

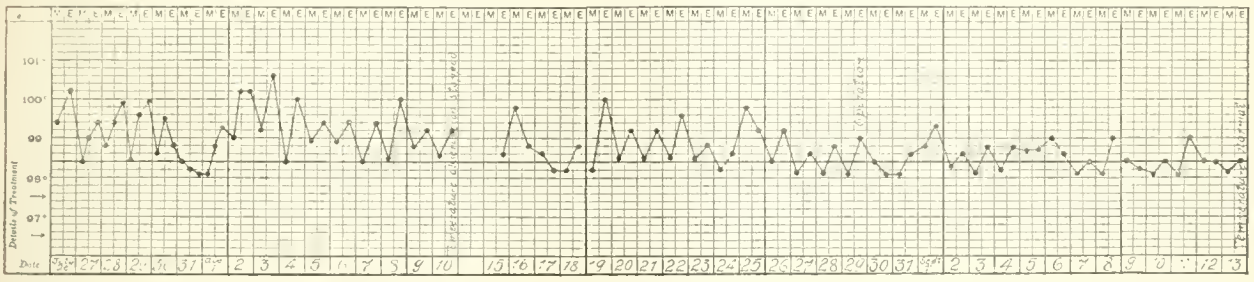

Chart 2

The treatment instituted was mercurial ointment locally to the swelling on the sternum, and potassium iodide internally, beginning with five grains and gradually increasing the dose. The pyrrhœa alveolaris was treated by having the teeth scaled and then giving a mouth-wash of Dobell's solution with hydrogen peroxide swabbed on the gums once daily. During the latter part of July, cod-liver oil and iron tonic pills were given. During August moderate doses of mercury were given by inunction for ten days, followed by pills of protiodide of mercury.

There was a decided improvement at first, and the swelling over the sternum apparently subsided, but the inflammation of the gums finally compelled the withdrawal of the mercury. The patient began to lose flesh and strength again. On

August 26 the potassium iodide was resumed and malt extract given as a tonic. The diagnosis at this time was changed to syphilis and the swelling over the sternum was believed to be due to syphilitic necrosis.

On August 28, under chloroform anesthesia, an exploratory incision was made. The periosteum was reflected and two areas of caries of the bone found beneath; one, three centimeters in diameter and the other about one centimeter in diameter, small and irregular. These were thoroughly curetted and irrigated, then a gauze wick was led through the periosteum and the incision closed above and below. There was immediate relief to the pain in the chest after the operation, and for nearly three weeks a decided gain in strength and health. The wound healed quickly and the sinus closed on September 23. On September 14 the potassium iodide was stopped and mercury again tried, but on September 28 it was necessary to withdraw the mercury, owing to an increase in the pyrrhœa alveolaris and the appearance of a new area of tenderness over the lower part of the sternum.

On September 30 a small nodular swelling was noticed over the right side of the frontal bone. This increased in size until on October 6 it was decided to give mercury again cautiously in a fresh mixture with potassium iodide. On October 11 the nodule on the frontal bone had increased to the size of a walnut, with decided evidence of fluctuation. On October 18 the mixed treatment had to be again withdrawn and ascending doses of potassium iodide were alone used, the patient taking 135 grains before the physiological action was apparent. The pain over the lower part of the sternum disappeared and there was a slight decrease in the size of the swelling on the day when he was discharged from the hospital and from the service, November 1. He also gained in flesh and strength and there had been no fever for nearly two months.

These cases are not only of interest in showing the difficulty of diagnosis in cases of tertiary syphilis with fever, but the results of the operative treatment indicate a possible cause for this hectic fever. Observation of the mercurial treatment also emphasizes the necessity of administering mercury with caution in such cases. Although it is a well-known saying that "mercury cures and potassium iodide relieves," both of these patients improved more rapidly when the iodide alone was used. The danger of large doses of mercury in syphilitic cachexia being realized, yet its use being regarded as a necessity to produce a cure of the disease, it was only after repeated trials, in both these cases, that the real value of the iodide was appreciated.

A MORE LIBERAL DIET IN TYPHOID FEVER.*

By THOMAS A. CLAYTOR, M.D.,

WASHINGTON, D. C.

PROFESSOR OF THERAPEUTICS AND CLINICAL MEDICINE, GEORGE WASHINGTON UNIVERSITY, PHYSICIAN TO THE GARFIELD AND TO THE UNIVERSITY HOSPITALS.

This subject has been approached with some hesitancy for two main reasons: First the profession, as a whole, is strongly opposed to more liberal feeding in enteric fever, and one who advocates it runs the risk of sacrificing, to some extent at least, the confidence which may have been reposed in him by his brother physicians; second, an argument in favor of a more liberal diet might be misconstrued into one for too full a diet, and thus do harm.

I wish to present to you the results in a small number of cases, twenty-six in all, which I have treated on a more extended dietary during the past year. The results have been no better, as far as ultimate recovery goes, than in cases treated with a more restricted diet, but my patients have been far more comfortable, happier, and have, I think, convalesced more promptly.

The treatment, dietary and otherwise, of all diseases has changed from time to time, but it must be acknowledged that typhoid fever, from the days long before it was separated from other continued fevers (1813–1837) to the present time, has been rather a notable exception. Following the precepts of Hippocrates, Galen, Celsus, and a long line of distinguished physicians urged a very rigid diet during the acute stage of fevers, consisting chiefly of barley water and the like. In the latter half of the seventeenth century the teachings of Thomas Sydenham, who followed a vigorous antiphlogistic plan, had a strong influence on the feeding in continued fevers. Water-gruel and barley-gruel represented his dietary with the addition of a few spoonfuls of broth several times a day. During the eighteenth century and the early part of the nineteenth, the diet became more liberal, but was exclusively vegetable. Farinaceous gruels, fruit juices, and soft fruits were allowed. Very restricted diet prevailed, however, until the time of Graves of Dublin, whose influence was felt in the latter part of the first half of the nineteenth century. He was considered to have very liberal ideas as to feeding in fevers. He recommended well-boiled gruel with sugar and lemon juice or panada, of which a spoonful was given every third hour. In France, Brossais, arguing from the basis that all febrile conditions depended upon gastro-intestinal irritation, urged a most rigid diet in fevers. The doctrines of Brossais were attacked by Trousseau, Hérard, Monneret and others, and were finally overthrown in 1857.

Milk did not come into favor until the last third of the past century, but since that time it has been almost the sole dependence in typhoid fever.

It would appear from the foregoing that there has been a gradual, very gradual, tendency to increase the amount of food given in continued fevers ever since the time of Sydenham, and I should not be surprised, if in less than fifty years, those looking back over our exclusively milk diet will feel much the same sympathy for our patients as we feel for those poor fellows of not so long ago who, though parched with thirst, were allowed little or no water. The argument advanced by the advocates of the milk diet is, that, on account of the inflamed and usually ulcerated condition of the small intestine in typhoid fever, liquid food should be given. They seem to forget that milk ceases to be a fluid the moment it reaches the stomach, and that all food which is properly prepared and digested reaches the ileum, the most common seat of greatest inflammation, in a more or less fluid form. In view of the latter fact it would seem that the food in typhoid fever only needs to be finely divided and digestible, and to be accompanied by a sufficient amount of water. E. K. Herring puts it rather aptly when he says, "It should be free from strings and stones and skins and bones."

It has been proved experimentally that the digestive and absorptive powers, during typhoid fever, fall off only five to ten per cent., so that impaired digestion is not sufficient argument in favor of milk alone.

*Read before the George Washington University Medical Society, November, 1905

It has long been recognized that typhoid fever is a general infection, the bacilli having been found in practically all the tissues of the body; the intestinal lesions, therefore, are by no means the whole matter for consideration

Curschmann's analysis of the causes of death in 580 cases of typhoid fever (Nothnagel: "Encyclopedia of Practical Medicine") shows: Severity of infection, 46.9 per cent.; intestinal perforation, peritonitis, 16.5 per cent.; hemorrhage, 7.8 per cent. Thus it may be seen that only a little less than half died from the severity of the infection, whereas a little less than one-fourth died from intestinal lesions. Taking these as representative figures, it is quite clear that we have twice as much to fear from the inability of the patient to withstand the severity of the infection, as we have from the intestinal lesions. It would seem equally clear, then, that the first indication is to maintain the bodily vigor at the highest point possible. It has also been suggested by Barrs (*British Medical Journal*, 1897) that starvation would tend to prevent the healing of ulcers in the intestine, in the same way as in similar conditions in other parts of the body. It also seems likely that if the patient were allowed a greater variety of food during the febrile stage, there would be much less likelihood of bad results from indiscretions during early convalescence.

For several years I have been inclined to break through the ironclad rule of almost an exclusively milk diet; so very cautiously and with many fears and misgivings have I done so. So great has been the prejudice in favor of an absolutely liquid diet, as represented by milk with the occasional substitution of animal broth or tea, that the physician is almost afraid to take the risk of suggesting any change, knowing full well that, should anything go wrong he would be held responsible, if not by the patient and his friends, certainly by the profession, because of reckless feeding.

Since typhoid fever cannot be aborted, nor influenced by any form of specific medication, our efforts are directed toward so ordering the general conduct of the case as to avoid complications and to hasten recovery.

The trend of thought of the present day is toward the belief that most diseases are due to specific poisons, and that recovery depends upon, either the exhaustion of that poison, or the development or an antibody of some sort, which renders it innocuous.

It becomes necessary, then, to keep the patient in the best possible condition to withstand the ravages of the disease until such time as recovery shall take place.

Since many are exposed to typhoidal infection who do not develop the disease it is very evident that some have greater resisting powers than others, and it is probably due to this fact that we have not all had the fever. It seems reasonable to suppose that a long attack is due, in part at least, to the inability of the individual to overcome the poison. Therefore, we should do all we can to develop the resistive power, or in other words, to keep up the strength of the patient. To accomplish this end we must give sufficient food. Now it is almost impossible to give milk alone in sufficient quantity to supply the needs of a man through a long illness, even though it comes nearer to being a perfect food than any other article.

Voit's table shows that the normal man of an average weight of seventy to seventy-five kilos (150 to 165 pounds) doing a moderate amount of work requires a total food value of 3,000 calories per day to maintain the body in good physical condition. It has also been estimated that the body at rest requires 2,300 calories. Now the man suffering from typhoid fever would certainly require a larger food value than the man at rest because of the greater energy evolved in fever, if from no other cause. This excess would be hard to estimate accurately, but it has been placed at 500 calories, which would bring the total food value requirement up to 2,800 calories, for a patient suffering from typhoid fever.

Now if 180 c.c. (six ounces) of milk, representing 200 calories, be given every two hours day and night, the total food value would, in twelve feedings be 2,400 calories; but few patients are wakened every two hours for food, so that nine feedings, at most, would be given, representing but 1,800 calories. Thus it is readily seen that the usual exclusive milk diet falls short by 1,000 calories, more than one-third of the supposed requirements.

Chittenden's experimental work in physiological economy has apparently proved that, so far as those in heath are concerned, a food value of 2,000 to 2,500 calories, representing about half the nitrogenous food previously supposed to be necessary, is quite sufficient to maintain a perfect bodily and mental equilibrium. Of course this new scale rather throws doubt on all former calculations as to the bodily requirements in health and to some extent also in disease. But aside from all economic calculations it is well known that an exclusively milk diet, six ounces every two hours, does not satisfy the craving for food. We also have the most practical evidence of insufficient nourishment in those suffering from typhoid fever in their enormous loss in weight. Of course we recognize the fact that no matter how carefully we feed these patients there will surely be a loss in bodily weight, but it need not be so great.

In selecting a diet for typhoid fever patients the following important points should be borne in mind: It must be highly nutritious; it must be easily digested; it must be innocuous; it should be palatable. The food must possess sufficient nutritive value to maintain, as far as possible, the bodily equilibrium. Since the digestive functions are likely to be somewhat impaired, the food must be of such a kind and so prepared as to throw as little extra work upon them as possible. The food must be innocuous. Neither by its coarseness, bulky residue, gas-producing or other properties, should it tend to cause the serious complications of hemorrhage and perforation. Outside of the comfort and pleasure which palatable food affords the sick man, Pavlov has shown that it has an important bearing on its digestibility.

It has been my custom of late to begin the treatment of a case of typhoid fever, no matter on what day of the disease it may come under my care, with the regulation six ounces of milk every two hours, night and day while awake. Animal broths are given in place of milk, to vary the monotony for those who can take milk, and as a substitute for those who cannot. Each day, after the subsidence of the more acute symptoms, such as headache, I ask the patient if he is hungry, and as soon as he replies in the affirmative a soft-boiled or poached egg is allowed, and if well borne, the number is gradually increased to three or more a day. The next additions are jelly or blancmange, custard, soft toast, the carefully selected soft part of baked apple, or rice which has been boiled four hours. The last to be tried are scraped beef or chop, very finely divided chicken and baked potato, the latter only when digestion seems specially good.

I do not want to be understood as advocating so full a diet in every case, but each case should be

studied individually, and when, from the condition a more liberal amount seems advisable, it should be given.

I cannot but believe that most of the foods mentioned are quite as digestible, far more palatable, and less likely, if anything, to cause perforation or hemorrhage by their local action or gas production than milk. It is well known that milk often produces tympanites, that it leaves a large residue after digestion, and is more likely to cause impaction than almost any other food. Often in typhoid fever large curds are detected in the evacuations. It is then customary to reduce the already insufficient supply of milk by further dilution. Why not try something else?

Before analyzing my tabulated list I would like to call attention to one case whose unusual severity has materially raised the averages. This woman had fever for 97 days, was in bed 127 days, and in the hospital 135 days. Of course such a lengthy illness is uncommon, but it must be included.

In the deduction of averages I have disregarded small fractions as immaterial.

I wish to thank Dr. Homer Fuller, late resident at the Garfield Hospital, for having taken from my histories the data in this table.

Average.	7	39	50	52	2	5	5				

Of these 26 cases all recovered. The shortest duration was 9 days, the longest 97, the average 39; the earliest day on which a patient was out of bed was the 22d, the latest, the 127th, the average, the 59th. The shortest stay in the hospital was 18 days, the longest 135, the average 50.7. (The last figures, relating to the number of days in the hospital, are of no value, as the date of admission was in some cases very late, while others left before they were completely recovered.) There were two relapses; in five cases one or more hemorrhages occurred, but in only one instance, as it happened, had an exclusively liquid diet been exceeded before the occurrence of hemorrhage. Delirium was present in five cases. Other complications were not more numerous than usual except pleurisy, which was twice recorded.

While I know that twenty-six cases form far too small a number from which to draw conclusions of any great value, yet it is my belief that the careful personal observation of even a few cases should be recorded, for it will require the weight of evidence of many clinicians to shake the implicit faith of the profession in the exclusive milk diet.

From my own experience I am prepared to say that the more liberal diet is certainly not deadly; if it possesses no special advantages neither does it show special disadvantages. The advocates of the more liberal diet, among whom I take my stand, claim that the patient is more comfortable; that the attack is slightly shortened; that convalescence is more prompt, and that neither relapse, hemorrhage, nor perforation is more frequent.

The advantage which is most apparent is the increased comfort of the patient. Typhoid fever is at best long and tedious, and we are all familiar with the days and weeks during which our patients clamor for more to eat. The pangs of hunger are much harder than nany other discomfort that they are called upon to bear after the first ten days of fever. Now if more liberal feeding does no harm this one advantage—the comfort of the sick man—is sufficient argument in favor of its adoption, but more is claimed.

F. C. Shattuck (*Boston Medical and Surgical Journal*, Vol. 148, 1903) reports a mortality of 10 per cent. in 233 cases on an exclusively milk diet, while the mortality was but 8.45 per cent. on an enlarged diet. Fitz's analysis of the cases of typhoid fever in the Massachusetts General Hospital (*Boston Medical and Surgical Journal*, 1899) shows that the mortality was less in Shattuck's cases, on a more liberal diet, than in those of his colleagues, on a milk diet; and that relapses were 2.9 per cent. less frequent in the liberally fed. W. H. Smith has brought these statistics up to 1902, and shows that in 563 cases, hemorrhage, perforation, and relapse were no more frequent among the more liberally fed.

Shattuck's diet list is about as follows: Minced lean meats, scraped beef, soft part of raw oysters. Soft crackers with milk or broth, soft puddings without raisins, soft toast without crust, blancmange, wine jelly, apple sauce, and macaroni.

Of course the way to become convinced is to try the system, but those who are interested will find instructive articles, besides those already mentioned, by Marsden (*The Lancet*, January, 1900), the late F. A. Packard (*Therapeutic Gazette*, 1900), Murrell (*Medical Brief*, St. Louis, 1900), Morris Manges (MEDICAL RECORD, 1900), and H. A. Hare (*Therapeutic Gazette*, 1904). The latter states that his attention was first called to this matter by an attack of typhoid fever, during which, though he had no appetite, yet he felt underfed. He felt that he was attacked on the one hand by the bacillus of Eberth and on the other that his powers of vital resistance were being reduced by partial starvation. Two of the most thoughtful articles on the subject are by J. B. Nichols (*American Medicine*, Vol. 9, No. 18, and MEDICAL RECORD, 1905). Thayer's translation of Bushuyev's article has attracted wide attention, and although the latter's results were excellent, I am not yet, nor do I ever expect to be ready to advise such a diet for typhoid fever patients as he advocates. It is rather too much on the order of that for a day laborer.

It is far from my intention to speak ill of the bridge which has carried so many safely over, and indeed, from long experience, I have a most wholesome respect for the milk diet in typhoid fever, but I do believe that the pendulum is making a belated swing toward more liberal ideas with regard to feeding.

1315 NEW HAMPSHIRE AVENUE.

THE CURABILITY OF TUBERCULOSIS.

By HENRY F. LANGHORST, M.D.,

ELMHURST, ILL.

I WISH, in brief, to report a few cases of tuberculosis that have been under my care during the past five years. As the results obtained were favorable, the review of these cases may tend to dispel the gloom that dominates the prognosis of tuberculosis and make the word sound less ominous.

These reports have not been thoroughly worked out since the sputum was not examined for bacilli and tuberculin was not used as a diagnostic aid, but since these aids to diagnosis are often uncertain, the possibility of making a diagnosis, on the symptom group associated with the physical signs, seems reasonable. We must remember that statistics show that tuberculosis, either healed or active is found in 80 per cent. to 90 per cent. of all people. Since only 12 per cent. die, the difference between 85 per cent. and 12 per cent. shows the great percentage of cases that recover. When one realizes the omnipresence of the tubercle bacilli and the many avenues through which infection may occur, these statistics do not seem excessively high. If the history of the cases, showing evidences of healed tuberculosis, in the lungs, were carefully investigated, the inquiry would reveal in many instances a history of prolonged or tardy convalescence following the zymotic diseases, especially measles, pertussis and influenza.

V——. Age three years. Family history negative. Child had measles, six weeks previous to my first visit. Cough persisted, child grew emaciated, refused to eat, had fever and chills. On examination found her greatly emaciated, drowsy, with rapid respirations, loose cough with loud râles, temperature 101°, and pulse 150. Physical examination revealed râles over entire chest, bronchophony over right apex posteriorly. Increased fremitus and dullness was also present. The child had lost about fifteen pounds in weight and presented an appearance which did not inspire much hope of ultimate recovery. She developed enuresis with an alkaline, foul smelling urine. Her teeth were rapidly decaying and numerous alveolar abscesses were present. She had subnormal morning temperature with afternoon rise to 101° to 102½°.

She was placed in a perambulator and was wheeled out in the fresh air every day. Her chamber at night was well ventilated and during the day was flooded with sunlight. Her diet consisted of milk, cream, eggs, rice, and other easily assimilated foods. She was given three drops of creasote carbonate after meals in milk. This was increased to eight drops. She was also given calcium hypophosphite in syrup after meals. Under this treatment she began to show improvement after the first week. The second week she began to observe things about her and at the end of the second month was able to walk unaided. She made a complete recovery in three months. Her enuresis yielded to hexamethylenamine and fluid extract of arbor vitæ.

R. B——. Age six years. Father had attack of pulmonary trouble while a young man, which got well however, after a season of out-door life in Canada. It was evidently tuberculosis. The boy had many attacks of false croup and had bronchitis every winter. Had pneumonia once. The family moved from Chicago to the country, seeking to benefit the boy's health. While out in the country the maid of the family was taken with tuberculosis, which her physician failed to recognize. The maid expectorated quite a good deal and was often left in charge of the boy. Her condition finally become serious and she left for Denver. Two weeks before the boy came under my care he had an attack of bronchitis following measles. His convalescence was slow and he continued to have fever. His appetite was poor and he was rapidly losing in weight. On examination a well-developed chest was found; limitation of motion on the left side was very apparent; his face was flushed and temperature registered 103°. The only evidence found was in the left side near the nipple. Here crepitant râles were found with bronchial breathing; fremitus was increased but dullness could not be clearly made out on account of the heart. His temperature would run up to 103½° every afternoon and was normal, until noon. His cough was troublesome and of a hacking character. The diagnosis rested between an unresolved pneumonia and tuberculosis. The subseqeuent course proved it to be tuberculosis. He was put in a sunny, well-ventilated room and given increasing doses of creasote carbonate (m. 3 to 10 t. i. d. in milk). Absolute rest was made imperative. Alcohol rubs were given when fever was high. In a week's time his fever did not exceed 102°. He was now taken out of doors every day in a go-cart and spent most of the time in the open air. He continued to improve so rapidly that at the end of two months his afternoon temperature was only 99½°. At this time, unknown to me, the parents took the child to Dr. N. S. Davis, Jr. to get his opinion, as they doubted the diagnosis of tuberculosis. He substantiated the diagnosis and recommended the out-door treatment. At the end of three months the temperature was normal and no signs of disease were present. The following winter he developed a sore throat, the culture showing a grip infection. He soon recovered from this, but for a week developed an afternoon rise of temperature. This soon disappeared, however, on the exhibition of creasote. He is well at this time (two years later) and is again in the city.

O ——. Age four years. No history of tuberculosis in the family. The boy was healthy until he contracted measles, which occurred about two months before he came under my observation. He continued to cough following the measles, and gradualy began losing both in weight and strength. He would lie in his crib with half-closed eyes, and was in a lethargic state. He refused nourishment and developed a jaundice. His stools were clay-colored and bowels were constipated. His temperature was 101° and pulse 160. His cough was loose and frequent. He was greatly emaciated and seemed too weak to even move his arms. The chest was filled with râles, and bronchial breathing was detected in both the apices posteriorly. This was very marked. This occurred in February. A good hot fire was continued day and night and the windows kept well opened. A screen was placed before the bed to protect him from draughts. He was given sodium phosphate to move the bowels, and small doses of nux vomica and hydrastis were given until the jaundice cleared. In addition to this he was given creasote carbonate in four-drop doses. He gradually improved. His appetite became better and the jaundice disappeared. His temperature never was excessively high, and remained normal after the third month. His cough did not

disappear until July. He was given calcium hypophosphite during the last three months with apparently good results.

P——. Age three years. At the age of one year she had an attack of pneumonia with delayed resolution. She was not expected to live at this time, and hovered between life and death for about three weeks. She subsequently recovered after a tardy convalescence. She contracted whooping-cough in August 1905, and the parents used different nostrums without result. In the middle of September I saw the child at my office and was surprised at the change that had taken place in an interval of two months, when I had last seen her. The child was constantly crying and making a conscious effort to suppress the cough. She was extremely emaciated. weighing only nineteen pounds. Every attempt at moving her would result in a crying fit which in turn would bring on a paroxysm of coughing. An eroding discharge issued from her nostrils. On the forehead were two small ulcers that she persistently kept picking. She would sink together and lie in a heap. She was unable to hold herself erect. Many râles were heard over the whole chest. The whole right side seemed congested, fremitus was increased, on that side, and percussion elicited dullness. A satisfactory examination could not be made. Her rectal temperature was 101°, pulse 140. She remained in about the same precarious condition the next month, during which time a troublesome diarrhea developed. In September her appetite began to improve and she gained in strength; her cough grew less and she became cheerful and would laugh and talk. This was considered a good omen, since she was so very irritable, whining and crying almost continually, the previous two months. At the present writing (November) she still continues to improve, and for the past week has been able to walk unaided. Very little hope was entertained for the recovery of this patient in the beginning, but a very hopeful prognosis can now be given. The treatment consisted of out-door life all the day, a well-ventilated room during the night, creasote carbonate from three to eight drops in milk after meals, dovers powder and chalk mixture for diarrhea, calcium hypophosphate in two-grain doses. Lime water was given with milk. Small doses of nux vomica and hydrastis were also given. In this case as in the others the calcium hypophosphite seemed to act very beneficially.

A——. Age twenty years. Student. Family history of pulmonary trouble. Had pneumonia twice. First came under my attention while suffering with an attack of tonsillitis with marked involvement of the glands of the neck. His temperature was 101°, the pulse 130. His pulse persistently remained rapid. The adenitis persisted after all evidences of tonsillar inflammation had disappeared Guaiacol ointment gradually reduced the swelling. An afternoon rise of temperature and a continued rapid pulse directed attention to the chest. He had a slight hacking cough which was attributed to a slight catarrh of the throat. His chest was the typical one generally associated with pulmonary tuberculosis, namely, a long narrow chest. Expansion was limited on the left side. Auscultation revealed bronchial breathing in left apex with prolonged expiratory murmur. Cogwheel respiration over left side. The vesicular murmur on right side was weak, assuming more of a bronchial quality. Impaired resonance over left side. In view of the physical findings and symptoms a diagnosis of incipient phthisis was made. He was requested to give up his school life and lead an active out-of-door life. He followed instructions and his temperature and cough disappeared. He is again pursuing his studies preparing himself for the ministry. He has been advised to abandon his aim and choose a life which will demand more out-door activity.

U——, student. Age seventeen years. Family and previous history negative. Complains of loss of appetite, weakness and cough. He attributes the cough to fumes from furnace in the department of mechanics. He has a slight fever 99°, pulse 90. Prolonged expiration in right posterior apex with cogwheel respiration. No dullness nor râles. Chest poorly developed. Was given nux vomica and Blaud's pill and five drops of creasote carbonate. He was kept from his studies and given out-door employment. He soon regained his strength and has grown quite strong.

Before mentioning another instance, I wish to describe in brief a case of glandular tuberculosis that seemed the focus of many infections.

W——. Age twenty-one years, was afflicted with tuberculosis of the cervical and axillary glands. The glands were repeatedly removed by Dr. A. Bevan but the process continued. Sinuses were present which discharged pus. This condition persisted for five years when he succumbed to tuberculous peritonitis. His sister developed a cough with loss in weight and an afternoon rise of temperature (101°). Physical signs indicative of tuberculosis were present. She was ordered from the house, and out-door life, full diet and creasote carbonate were prescribed. She made a symptomatic recovery. Another sister living below had an ulcer on the tibia which took on a tuberculous appearance. A boy living three doors away developed an attack of tonsilitis with involvement of the glands of the neck. The glandular enlargement persisted. The glands were removed, once, by Dr. E. Senn. They recurred but since have become smaller and are held in abeyance by ultra violet ray treatments. In the next house to this subject of glandular tuberculosis, a school boy of eight years developed a cough accompanied by rapid emaciation. His family history was unquestionable in reference to tuberculosis. He had no previous pulmonary affections. His pulse varied between 100 and 120. Temperature varied between 101° and 103°. The physical signs were positive. To the right of the spinal column at the sixth dorsal vertebræ marked bronchial breathing with bronchophony could be detected. Crepitant râles were present and dullness was elicited. He was taken out of school, out in the fresh air, given a liberal supply of food and with this carbonate of creasote and syrup of calcium hypophosphite. He responded immediately and in a month his temperature was normal and the cough nearly gone. He had gained about six pounds. He has made a perfect recovery and his lungs seem perfect.

These instances are but a few of many that could be recited. They are occurring every day in the practice of all physicians. Many are not recognized, but under tonics and rest recover spontaneously, the only evidence of the tubercular process being a scar in the lung.

That this disease is yielding to the well-directed efforts toward its extermination is attested to by the figures of the statistician. The key note of success in the treatment of this disease is an early diagnosis. It does not require a laboratory, nor extraordinary diagnostic acumen to make a

diagnosis of incipient phthisis. A careful study of the patient and a proper interpretation of the physical findings will result in an early diagnosis. Proper therapeutic and hygenic modalities now directed against the invading enemy will so reinforce nature as to make her conquest an easy one. Once the enemy has been repulsed we can assist in perfecting a system of defense that will withstand the daily onslaughts of this ubiquitous germ.

THE CONSERVATIVE TREATMENT OF URETHRAL STRICTURE.*

By G. MORGAN MUREN, M.D.,
BROOKLYN, NEW YORK.
GENITOURINARY SURGEON TO THE WILLIAMSBURGH HOSPITAL.

To many it may seem that the last word has been said upon urethral stricture, that the various forms of treatment are clearly laid down in the modern text-books on genitourinary surgery, and that there is little left to be written upon this subject.

On the contrary, I believe that the average general surgeon, and even some genitourinary specialists, have a very wrong conception of the condition and the treatment usually indicated. Many of these men are teachers in the medical colleges, and the students are told that urethral strictures should be dilated when that is possible, and when it is not they should be cut, either by internal or external urethrotomy. This is correct, and while certain men may have very proper and well-defined ideas as to when dilatation is impossible and when cutting should at last be advised, there are too many surgeons who have but a poor understanding of the possibilities of dilatation or else too little patience and practice to manipulate the tight stricture of small caliber. Cutting, therefore, is frequently advised in cases that should be dilated.

Strictures fall into the surgeon's hands in one of two ways: The patient has retention, and his family physician is unable to enter the bladder with either his soft rubber catheter, silver catheter, or even perhaps with the Gouley instrument, and the surgeon is called. Other cases present themselves for treatment without any acute symptoms, the patient knowing that he has stricture and appreciating an increasing difficulty in voiding urine, becomes alarmed and seeks his physician's, and, subsequently, the surgeon's aid.

I venture to state that in both classes of cases, if the stricture be fairly tight and dense, the surgeon will recommend some cutting operation. He will be particularly likely to so advise the patient, if the latter is a working man who has little time and money to devote to the improvement of his urethral caliber. It has long been common teaching that the man of this class can be cut and returned to his regular occupation almost immediately, while time can only be spared for dilatation by the individual of larger means and greater leisure.

This is one of the greatest errors that have been passed to succeeding generations of surgeons. The poor man, after a so-called successful urethrotomy, leaves the hospital, passing a greatly improved stream of urine, and feeling quite confident that his trouble is over. He is told that sounds must be passed at more or less frequent intervals for the succeeding year, and that if, after that time, no contraction occurs, he will be cured. That he does not in the great majority of cases return for this treatment is a matter of common knowledge to all surgeons in institutions where much of this work is done.

It requires but little knowledge of surgical pathology to appreciate the fact that cut surfaces in constant apposition, are more than likely to unite, even if urine is regularly passed over them, and this is the condition after all internal and many external urethrotomies. Agnew[1] said: "However valuable may be incision, it must not be deemed a radical cure for stricture, notwithstanding what is said to the contrary by sanguine urethrotomists. The 'splice', of which so much is said, and which occupies the gap between the sides of the divided parts, is granulation tissue; and the resulting cicatrix will always retain that invincible power of contraction. The tendency to coarctation in the canal, it is true, is lessened, but it is not destroyed; and hence the patient must be instructed to pass a metal sound once or twice every month if he expects to keep out of the hands of the surgeon at some future time."

The brilliant results claimed by active urethrotomists have no doubt in many cases been due to the fact that the supposed stricture was really a point of physiological narrowing in a normal urethra.

Dr. Otis taught that the urethra was a tube of even caliber from the bladder to the meatus; and that any encroachment upon its lumen was a stricture, and should be cut. Four points of narrowing exist in the normal urethra. (1) At the meatus. (2) At the proximal end of the fossa navicularis. (3) About midway in the pendulous urethra. (4) At the bulb. It is easy to understand that "splicing" a normal urethra in a young man will "cure" his "stricture".

The main objections to cutting operations are the following:

1. Several weeks' detention from business, a very serious drawback in these days of active struggle for existence.

2. The fact that, after operation, the individual has to be treated for a year or more, in practically the same manner as if no operation had been done, and his stricture had been gradually dilated.

3. The mortality rate. This is a much disputed point, but I believe it to be at least 5 per cent. in both internal and external urethrotomies.

J. William White[2] makes the following statement regarding mortality from internal urethrotomy: "The practitioner who decides to cut a stricture anterior to the bulbo membranous juncture, must do so with the full knowledge that there are at the very least two chances in a hundred of losing his patient. There should certainly be definite and well grounded reasons for accepting this risk, and the operation which involves it should show results unmistakably superior to those of gradual dilatation—a procedure with practically no mortality."

A trifling operation that is so easily done that it is done far too frequently, is meatotomy. While it is often necessary to enlarge a meatus, it is easy to cut too freely, and the resulting lack of resistance to the stream of urine sometimes interferes seriously with the muscular tone of the bladder. The gaping meatus also invites venereal infection.

I will not enter in detail into the treatment of stricture by gradual dilatation. This paper has been written as a plea for this more conservative means of treating stricture, and I will only mention briefly what I believe to be the important points in a method of treatment that is not new, but is neglected by some colleagues.

In men beyond middle age the anterior urethra should be thoroughly flushed before any instru-

*Read before the Associated Physicians of Long Island, October 21, 1905.

mentation. In younger men it is safer to make this a rule, although I do not believe that the sound bladder is easily infected by the germs ordinarily found in the anterior urethra.

As a lubricant for urethral instruments, vaseline should never be used. It has been found in the center of calculi in the bladder, and is difficult to remove from instruments. The best lubricant is made from Irish moss, and contains a small percentage of formalin. The lubricant should never be applied to the instrument by the hand of the surgeon, a common and most unsurgical procedure. It should be dropped from the container upon the meatus, and the sound or other instrument passed through it.

In endeavoring to find the opening in a stricture with the filliform guide, I have found filling the urethra with a number of the straight instruments, and successively attempting the passage of each, to be more successful than the use of the instruments with the variously twisted ends.

Most of us were taught to never use force in the passage of sounds. This I believe to be good teaching, and should be followed by those of little experience in urethral instrumentation. If it were lived up to by the genitourinary surgeon, many dilatable strictures would have to be cut.

In the use of tunneled sounds in very tight cases, without force the instrument would never enter the bladder. This is equally true of larger plain sounds. How much force can be used, and how to direct it, can only be learned by experience.

It is good practice to irrigate the bladder and urethra after any instruments have been passed. In some tight strictures, this is exceedingly painful, and I therefore instruct my stricture patients with healthy bladders to hold their urine for a couple of hours before treatment. It is voided immediately after dilatation and irrigates the urethra without discomfort to the patient.

Most authorities advise the passage of two sounds at each treatment, one to be the size of the largest passed at the previous treatment, and the second, one size larger. I have found it more comfortable for the patient to pass one sound, increasing one number each time.

When it seems undesirable to enlarge a meatus that will not admit a sound of proper size, one of the several dilators may be used. The one in most favor to-day is Kollmann's, with four arms. I do not believe, however, that any dilator can massage a stricture as well as the smooth, solid sound.

The element of spasmodic stricture is usually added in cases of retention due to true stricture. On this account it frequently happens that not even a filliform guide can be passed. Under general anesthesia this spasm is relieved, and instruments can frequently be passed with little difficulty.

Strictures due to gonorrhea may occasionally be seen that require cutting, but I believe they are few and far between. Certain congenital strictures, and those of traumatic origin require operation. The operation of choice in strictures anterior to the bulbo membranous juncture is that suggested by Reginald Harrison;[3] combined external and internal urethrotomy. This with perineal drainage gives absolute rest to the divided parts.

In closing I will report several cases that I believe illustrate the value of this method of treatment.

Case I.—J. F. æt. forty-nine years, was referred to me on May 13, 1905, at 1:30 A.M., by Dr. F. J. McDonough for retention of twenty hours' duration. I was able to relieve his retention with a small Gouley catheter. At 9:30 A.M. of the same day he again applied for relief, and was catheterized with the same instrument. He gave the following history: Several attacks of gonorrhea, the last in 1886. Was operated on for stricture by a prominent general surgeon of Brooklyn in 1900, internal urethrotomy. Was up and about the ward a day or two after operation and left the hospital a week later, able to pass a good stream of urine. He was instructed to report at frequent intervals for the passage of sounds. This he never did. He had three attacks of retention in the year before I saw him. All relieved with soft catheters. During the six weeks following his first visit to me, I dilated his stricture to 25 French, after which he discontinued treatment.

Case II.—J. B., æt. twenty-four years, referred to me by Dr. Sewell Matheson, July 24, 1905. He had first consulted a well-known Manhattan specialist who was unable to enter his bladder with any instrument, and who told him that an operation would be necessary. History: Had gonorrhea eight years ago, and for the past five months had noticed increasing difficulty in voiding urine. His stricture, which was at the bulbo membranous juncture, was passed without special difficulty with an 11 French tunneled sound. He is still under treatment, and this week I passed a 26 French sound. This case well illustrates the folly of cutting the poor man. This man was in receipt of a very moderate salary; his wife nearly at term, and several weeks in the hospital would have been a great hardship.

Case III.—G. W., aged fifty-one years. Was taken in the ambulance to the Williamsburg Hospital July 9, 1905. Retention for sixteen hours. No previous trouble. No history of gonorrhea. Several physicians had endeavored to catheterize him without success. The only instrument that could be made to enter his bladder was a filliform guide. He was anesthetized with ether and the Gouley catheter passed with some difficulty. Since then he has been dilated to 28 French and is still under treatment.

Case IV.—A. H., aged twenty-seven years, referred to me by Dr. A. C. Jacobson, August 15, 1905, by whom he had been treated for two attacks of retention. The first time I saw him was in the hospital where Dr. Jacobson had sent him, feeling sure that some operation would be necessary. I was able with the use of considerable force to pass an 11 French tunneled sound. This was followed by free bleeding. Since then I have been able to pass larger sounds up to 24 French, and he is still under treatment. There is some bleeding after each dilatation. This man was operated upon by a surgeon in Manhattan four years ago. Internal urethrotomy. His stricture was dilated for some months after the operation, contraction occurring again later.

Case V.—A physician came to my office at 6 A.M. on May 27, 1905. He had been unable to urinate for the preceding seventeen hours. Three preceding attacks of retention. Gonorrhea ten years ago. Only a filliform could be passed to the bladder, the effort to introduce a Gouley catheter along the filliform, produced very free bleeding.

He was taken to the hospital, anesthetized with ether and the Gouley instrument passed quite easily. He has been dilated to 24 French, and is

still under treatment, which I regret to say he has not continued very faithfully.

THE SCHWARTZE-STACKE OPERATION IN CHRONIC SUPPURATIVE OTITIS MEDIA.*

By J. J. THOMSON, M.D.,

NEW YORK.

ASSISTANT SURGEON, MANHATTAN EYE, EAR, AND THROAT HOSPITAL.

For the benefit of those who are not familiar with this operation, I will describe it in a superficial manner, without speaking of the technique in detail.

After throwing the ear forward as in an ordinary mastoid operation, the antrum is entered, and all the bone intervening between it and the attic of the middle ear is removed, together with a considerable portion of the posterior canal wall, thus converting the middle ear, the attic, the antrum, the additus, and the bony canal into one cavity. Care is taken to carefully investigate every recess, where disease may be present, and to obliterate it. Special care is required in this respect in the region of the attic, and additus, and the tegmen of the antrum. The middle ear will usually be found to contain a large quantity of granulation tissue and detritus, especially where the suppuration has extended over a period of months, and this together with the remains of the ossicles, is carefully removed. Indeed in cases of long standing not only granulation tissue and carious ossicles, but even sequestra extending up to the dura are often found.

It will be seen that it is practically impossible for any area of unhealthy bone to remain obscured in this operation, for everything is laid bare for inspection, and the dissection may be carried as far down the mastoid as is necessary to thoroughly eradicate every particle of necrosis, even the tip may be removed if necessary, without seriously interfering with the subsequent progress of the case, or the production of marked deformity. So much for the bony excavation; and now the membranous canal remains to be dealt with. This may be done in several ways. The method that appeals most to me is that of Körner. An incision is made in the membranous canal wall, above and below, extending as far outward as the concha. The skin is dissected from the underlying structures in the intervening space, giving a tongue-like flap. The underlying structures are then cut away and sufficient of the cartilage removed to allow the flap to fall gracefully into place. The posterior wound is then closed and all subsequent dressings are done through the canal. By introducing a speculum the whole interior of the cavity may be illuminated and inspected at every dressing, and herein lies one of the greatest advantages of the operation, for no matter what emergency may arise or what conditions may develop, they are directly under our observation, and are very accessible for treatment. Exuberant granulations can be either curetted or controlled with caustics, any tendency toward eustachian catarrhal conditions is readily treated, and as a rule in about six or eight weeks the entire cavity has epidermatized and is dry, leaving the patient with practically no deformity, and entirely freed of an offensive discharge, or a bony necrosis, that every day was a menace to his life.

Now the question arises, what are the indications for this radical and delicate operation, what are the conditions that render it justifiable, and what are the conditions, that in chronic cases, to the experienced and conscientious otologist, render its performance imperative, as a safeguard against future trouble?

I think a discharge that, in spite of careful treatment, has continued for over a year, may be characterized as a chronic one, and this I think, when all other means have failed to effect a cure, is a justification for the operation. Even more so is a discharge that will remain quiescent for a while, only on the slightest provocation to break out anew, especially if the hearing be impaired.

In cases showing exacerbations of that kind, there is no doubt, even though for a while they may appear to be cured, the primary etiological factor remains, and though it may not be so serious as other forms to be mentioned later, it is always an embarrassment to its possessor, and a tax on the general system, besides offering a favorable condition for the beginning of an acute mastoiditis. How often in cases of this class do we see an acute mastoiditis develop, possibly after the existence of intermittent discharge for years, and mastoiditis is always a serious condition even though operation be early resorted to. We occasionally see these cases terminate fatally, owing to extension of the disease to the brain or sinus, whereas if operative interference had been instituted years previous, the process would have been limited to a smaller area, and these important structures never would have been reached.

Another condition that occasionally accompanies intermittent purulent discharge, is chronic mastoiditis, in which there is an attack of headache, slight otalgia, furred tongue, and slight tenderness over the mastoid, with or without sagging of the posterior canal wall. The temperature may not be high, or there may be none at all, but nevertheless there is the mastoid tenderness, and a chronic inflammatory process is in progress. These attacks may disappear for months, only to return on the slightest provocation, and I consider they are a justification for an exploration of the mastoid process, and if necessary the radical operation. I have seen a great number of these mastoids opened where one could not help but be in doubt as to the condition he was going to find, but where it was considered advisable to give the patient the benefit of the doubt, even at the risk of opening a healthy mastoid. Almost invariably the antrum and mastoid cells are found to contain either free pus, or granulations in a process of disintegration, and not infrequently the mastoid process is involved from the antrum to the tip, and isolated pockets may even be found in the cells behind the sinus. One is frequently astonished at what extensive trouble may exist without any other manifestations than slight attacks of pain and tenderness. In most cases of this kind a simple Schwartze operation is inadequate and a more radical procedure is necessary.

So much for the simple purulent discharge, but the cases about which I wish especially to speak, are those which have been going on for a greater or less time, with the presence of granulations in the middle ear, or polypi in the canal; a fetid discharge exists, and a bony necrosis is present in the attic, slowly but surely making its way upward to the brain, or backward to the lateral sinus.

* Read before the Mount Vernon Medical Society.

The hearing is usually markedly impaired, and these are the cases in which I consider one is not justified in allowing the condition to continue. In doing so we are doing an injustice to our patient, for a greater menace to his life can scarcely be imagined. No surgeon at the present time would think of allowing a necrosis of bone in any other part of the body to progress for months, and years, without active interference, especially if it were approaching a joint or other important structures, yet here where an undoubted necrosis exists, in a far more dangerous locality, it is frequently deemed safe so long as the discharge, the very indicator of necrosis, continues free.

We should not lose sight of the fact that about 90 per cent. of all brain abscesses, and nearly all cases of lateral sinus thrombosis are due to suppuration extending from the middle ear, and it is not in cases of acute infection or acute mastoiditis, that these complications most frequently occur, but in the very class of chronic cases of which I have been speaking, with or without an acute condition being grafted on. Strange though it may seem, these conditions are sometimes very difficult to diagnose, and I do not doubt that many such cases have terminated fatally without the true location, or the true nature of the trouble being known. In no other way can the great increase in the number of these cases being operated on at the present time be explained. I think there is no doubt many such conditions have been mistaken for something else, in fact in a few instances I have known such to be the case. One young man's history in particular will illustrate what I mean. He was coming to one of the clinics at the Manhattan Eye and Ear Hospital, at rather lengthy intervals for a chronic aural discharge, accompanied by the formation of colesteatomatous masses in the middle ear. On one of his visits a polyp was discovered in the canal, and its removal advised, for which purpose he entered the hospital. The temperature chart revealed the fact that in the evening he was running a temperature of 104 degrees, which fell to normal in the morning. On questioning him he said he had malaria, and had been under treatment for it for some time. He had been losing weight and was emaciated and sallow, and had occasional chills. In addition to his septic symptoms, on close examination slight jugular tenderness was found, but there was no mastoid tenderness. These signs and symptoms, in connection with cholesteatoma in the middle ear, led me to the conclusion that he had lateral sinus thrombosis with septic absorption, and the usual operation for exposure of the lateral sinus was performed. The following condition was found: On opening the mastoid a large amount of cholesteatoma was found in the antrum and middle ear. The sinus was opened and found to contain a disintegrating clot, extending as far as the jugular bulb. Considerable pus was found surrounding the sigmoid sinus, the bony covering of which was entirely destroyed. Yet that young man showed very few symptoms localizing the trouble to his ear. Of course the jugular vein was ligated and resected, and the clot thoroughly removed. The neck wound, and that behind the ear healed kindly, but the case terminated fatally from pulmonary abscess and emypema, as such cases frequently do. That is typical of the manner in which these cases may be overlooked. He doubtless never had malaria, the blood at no time showing the plasmodium, but owing to the fact that he had chills and sweats, he was put on maralial treatment without inquiry regarding his ears. I think that such cases will continue to occur until where there is any doubt the ears are examined as a routine practice, because patients who have suffered for years from otorrhea, become so accustomed to the condition, that they consider it a part of their normal existence, and fail to mention it altogether.

Brain abscess with or without a marked rise in temperature, with its lassitude and mental depression, coated tongue, and headache, is very liable to simulate typhoid fever, and other general conditions, and for a long time be overlooked. These errors which are indeed very difficult to avoid, are undoubtedly additional evidence of the gravity of neglected middle ear suppuration. When these complications have occurred is not the proper time for successful intervention; it is too late then, for the large majority of such cases terminate fatally, but the proper time is as soon as necrosis in the attic and extending toward the antrum can be diagnosticated. Meningitis also is frequently due to extension of infection from the middle ear through the thin plate of bone forming its roof, and this complication, like the others, is generally fatal.

Besides these graver possibilities, one possessed of a foul discharge is hampered in business and handicapped in life, and occasionally avoided by his friends. The very consciousness of such a condition must produce a worry detrimental to even the most robust. Now of course this operation has its difficulties, and its dangers, not so much to life, but to that which is cherished almost as much, personal appearance. There is always the possibility of getting a temporary or even a permanent facial paralysis, but this is not a probability, especially in skillful hands, although one can never tell when he will be so unfortunate as to get so unhappy a result. I have seen operations, where apparently the technique was faultless, and where no facial twitch was observed, followed by well marked, but temporary facial palsy. This may be due to injury or traction on the chorda tympani nerve, to concussion during the operation, or to hemorrhage into the Fallopian canal, and they usually clear up in six months or a year. The external semicircular canal is also exposed to injury, which is followed by dizziness and nausea of a severe type, and occasionally by leaking of cerebrospinal fluid. The dura or lateral sinus may be exposed, but as a rule these are not serious mishaps, beyond possibly delaying the closure of the posterior wound for a short time.

Now what are the results to be expected, and what is the status of the operation as a cure for chronic middle-ear suppuration. As a rule the results are very gratifying indeed, as you will see from the cases I present this evening. The deformity cannot be noticed on casual inspection, and it requires close observation to notice that anything has been done. Skin grafts, inserted either at the time of operation or subsequently, are thought by some to hasten the healing, and do so in some cases, but my personal experience with them and that of many of the men whose work I have watched, is that they are unsatisfactory, and I think that epidermatization occurs almost as rapidly without them. A very important factor in obtaining a good result is careful after-treatment, and no matter how skillfully the operation may be done, if this is neglected failure is very likely to be the outcome. With regard to the hearing it is in nearly all cases impaired before the operation, and no improvement should be expected; on the other hand it may be a little worse, but occasionally it is improved. This may be due to the removal of

the carious ossicles, and granulation tissue, that filled the middle ear. I have in mind a young man on whom a mastoid operation was done on both ears, about two years ago, and owing to imperfect healing of the wound, and continuous discharge from the canal, a Schwartze-Stacke operation was done on the right side, about one year ago. It did very nicely, and gave the young man no trouble, while the hearing was almost double what it was in the left ear. The rapidity of healing, and its permanency depend a great deal on the thoroughness of the operation. Every particle of bone showing any tendency to necrosis should be removed, and the surface of the bone carefully inspected for sinuses. In like manner the amount of deformity, which I have said in most cases should be very slight, is governed largely by the amount of cartilage that is removed from the auricle, and the form of cutaneous flap that is made. However, I do not think the deformity in the soft structure is a consideration in the more serious class of cases, for here the operation is a necessity, and to me seems about the only rational and surgical manner of dealing with so treacherous a condition.

Now to consider it as a cure. It is really the only method that can be suitably applied to all cases. No doubt we have all had the same experience in douching the ears, and in treating them by the dry method. In some we succeed in arresting the discharge for a time at least, in others we fail entirely; but these more conservative measures should be given a very thorough trial, before we submit a patient to so serious an operation as the Schwartze-Stacke. It is only in cases where all other measures have failed and necrosis surely exists, that we resort to it. When we consider the conditions in the middle ear we can readily understand why we fail so frequently in our efforts to effect a cure. The cavity is imperfectly drained by the eustachian tube, and also by any opening that may exist in the drum, and besides being itself subdivided by the ligaments, it communicates with so many bony spaces and cells, that it is almost impossible to thoroughly clean it by any amount of douching.

The simple Stacke operation which was devised for the cure of otorrhea is not adequate for the reasons I have already mentioned, namely, that while the necrosis existing in the attic, and around the tympanic ring may be removed, we are still ignorant of the condition of the antrum, and communicating mastoid cells, and the folly of dealing with necrosis in the middle ear, and leaving the antrum full of granulations and infected débris is at once apparent. Moreover, in the simple Stacke operation there is greater danger of injuring the facial nerve, because we cannot see the surrounding parts so well, and we have not so definite and well-defined landmarks to guide us.

Before closing, I would mention another class of cases coming under the head of chronic suppuration, to which this operation is admirably adapted. It is those where, following a chronic discharge, an acute mastoid trouble has developed. If when dealing with a case of this kind the surgeon merely opens the antrum and allows the pent-up pus to escape he has far from completed his work. He cannot be assured that there does not exist in the attic and surrounding parts a necrosis of which he is ignorant, and no doubt this is the reason so many mastoids do not heal promptly, and drag on for weeks with a discharge both from behind the ear and from the middle ear itself. In no other part would such a suspicious area be left uninspected, and the only way in which we can properly, and thoroughly explore it, is by the removal of the posterior canal wall. When we have done this we have laid bare the entire chain of bony spaces, and no focus can remain unobserved to continue the infection and discharge. I feel sure that with added experience, and care in the selection of proper cases the Schwartze-Stacke operation will grow in favor, for undoubtedly there is no other operation that in chronic otorrhea, or in acute exacerbations of chronic conditions, gives the same completeness, and the same thoroughness; no other operation so universal in its application, and none which to the surgeon gives the same sense of security, in cases that at times are fraught with the greatest danger.

DISPLACEMENT OF THE FALLOPIAN TUBES TO PRODUCE STERILITY.

By A. E. ROCKEY, M.D.,

PORTLAND, OREGON.

As there are occasional instances when an abortion is justifiable as a necessity in saving life, so also are there conditions in which the possible occurrence of pregnancy would expose the patient to danger that it is most desirable to avoid. Ordinary measures unhesitatingly and very properly recommended under such circumstances are not infallible and around their fallibility hangs a perpetual cloud of uncertainty fraught with much anxiety. If the truth of these statements be admitted, and it is believed that abundant proof of their truth is not wanting, then a method of safely and positively insuring sterility should have a proper place in gynecological surgery.

The following cases are quoted as illustrating types in which the writer believes such an operation justifiable.

Mrs. A., farmer's wife, age 32 years, married ten years. Three confinements at term and one induced abortion. First labor tedious, but normal. Living child. The limbs were somewhat swollen in the last weeks of pregnancy, but no examination of the urine was made. Second labor, urine albuminous, puerperal eclampsia, instrumental delivery, child lived, convalescence tedious, could not nurse child. Third labor, same history, but conditions more severe. Child still born. Albumin was present for several months after labor. When pregnancy occurred again, abortion by curettement was advised and performed by two physicians, personally familiar with the history of the case. Subsequently the patient was sent to me for repair of cervical and perineal lacerations. In addition I recommended displacement of the tubes to insure sterility. It was accepted and carried out according to the technique to be described later. This is the youngest woman on whom I have performed this operation.

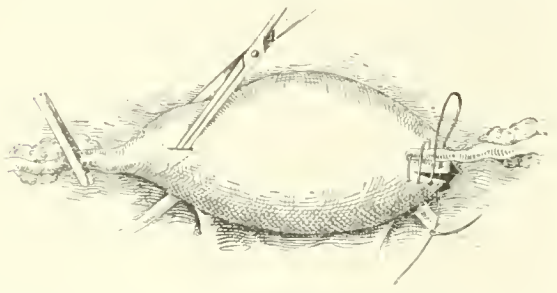
Mrs. B., age 39 years. Six confinements at term, with living children and two miscarriages, one at three and one at five months. Deep cervical laceration. Perineal laceration through anal sphincter. Vaginal outlet much relaxed. Complete uterine prolapse and rectocele. General health very poor by reason of debility. Patient emaciated and tissues flabby. Through an anterior vaginal incision and separation of the bladder, ample room was obtained easily to deliver first one cornu and then the other of a rather large uterus. The tubes were displaced, vaginal incision closed with rows of continuous catgut sutures, folding the tissues into a heavy column to support the bladder. Perineal floor repaired. Great improvement in general health resulted. The writer does not ordinarily favor the secondary repair

of cervical or perineal laceration of moderate severity during the childbearing period, as difficult labor and recurrence of the injury is prone to follow. Such repair may indeed cure a long-continued sterility, and pregnancy and parturition follow. There are conditions, social and physical, in which such a result is a most happy one, but there are others in which it may be followed by a train of undesirable, not to say dangerous consequences.

The following case will illustrate the cure of sterility by repair and reposition of the uterus.

Mrs. C., age 42 years. Youngest child 19 years; no pregnancy since; general health poor; patient emaciated and nervous. Right kidney prolapsed to brim of pelvis and fully movable, uterus retroverted. Cervical and perineal lacerations of moderate extent. Nephrorrhaphy, ventral suspension of the retroverted uterus, and repair of the lacerations was followed by great improvement in general health. Within a year she became pregnant. According to last news from this patient, who lives more than a thousand miles away, she was in the sixth month of pregnancy, which was progressing normally except for some abdominal pain which the attending physician said might be due to the ventral suspension (peritoneal only). In this case, the event is one desired and it is to be hoped and it is believed that a safe delivery may follow.

There are, however, conditions, both physical and social, in which it would be better for the patient to bear the ills she has than to incur the dangers of



pregnancy in the years nearly approaching the time when by the decree of nature the woman is, by the menopause, to be made incapable of bearing children.

If cervical repair in the years nearing this period is prophylactic against malignant disease, and there are those who support this statement by statistics and arguments, then surely there are cases in which chronic inflammatory disease of the cervix should at this time be cured in this way. If the purpose of these and other repair operations is to protect life and improve the general health, then it would seem to be poor ethics to expose the patient to the recurrence of the same conditions in addition to the other burdens if it could be avoided.

Another class of cases in which the procedure is a proper one, is in those women over forty years of age, where a peritoneal ventral suspension is not sufficiently strong to cure an extreme prolapse or a procidentia. Here a firm high ventral fixation gives the best results. Such an operation, however, is not advisable in the presence of a possible occurrence of pregnancy. To perform it would simply be to invite the danger of abortion for the relief or the disasters incident to a mechanical dystocia. Of course the woman may struggle along with makeshift relief by pessaries or plastic operations until the change of life occurs. But why wait for it? Pregnancy at this period and in this class of cases is seldom desirable or advisable. The following cases are illustrations of this type.

Mrs. D., age 41 years, youngest child seven years. Three years ago had an operation performed in an Eastern city for repair of cervical and perineal lacerations and ventral suspension by Kelly's method for retroversion. From this time on she became a victim of vesical irritation by reason of pressure of the anteverted fundus on the bladder. The woman was not neurasthenic. Operation: Abdomen was opened through line of former incision. The peritoneal attachment of the uterus had stretched into a band about the size of a lemonade straw and about four inches long. Displacement of the tubes and high ventral fixation were followed by immediate relief and permanent cure.

Mrs. E., age 45 years. Nine children. Last delivery six months ago. Instrumental delivery on account of inertia of the uterus. Child died on second day. Present condition, poor health and general debility. Vaginal outlet much relaxed. Uterus and bladder prolapsed, cervix lacerated. The uterus was curetted, lacerations repaired, abdomen opened through a short transverse incision, tubes displaced, and ventral fixation done.

In making this argument for the propriety of a preclimacteric production of sterility, it must be distinctly understood that we are not recommending it as a routine practice. We are only contending that there are cases, of which illustrative types have been cited, in which it is not only justifiable and proper, but in which we may consider it an imperative duty

The method I have to propose is the displacement of the uterine end of the Fallopian tubes. It is accomplished by three snips of the scissors and three stitches for each tube. It requires but a moment of time and adds nothing to the risk of an abdominal operation done for any other purpose. When the fundus of the uterus is to be exposed for this operation alone it may be done either through anterior vaginal or a very short suprapubic incision. The vaginal route is advisable for this operation only when the vaginal outlet is much relaxed, or when anterior colporrhaphy is to be done for the support of a cystocle. In these cases, the room is ample, and the surgeon of experience in vaginal operations on the body of the uterus can easily perform it in this way. This route, however, is more difficult and should not be undertaken unless the operator has had practice in this class of work, for there is some danger of injuring the bladder or ureters.

Abdominal incision is easier, and preferable. The writer uses almost universally the short transverse incision described in the Medical Record of November 7, 1905, not only for this, but for other intrapelvic operations.

The technique is as follows: When the cornu of the uterus is brought into the field of incision, seize the tube near its uterine end with a pair of forceps. Thrust the sharp point of a pair of scissors into the cornu, and cut out the uterine end of the tube by a V-shaped incision with two cuts of the scissors. Catch the wedge-shaped point of the excised end of the tube with the forceps, draw it out a little between the partly closed blades of the scissors and cut it off. The severed end of the tube will then slip ino the peritoneal sheath and be completely covered by it. Pass one catgut stitch through this cuff, then through the fundus posterior to the inner end of the V-shaped incision from behind forward and tie it, thus fastening the closed end of the tube back of its original position. Pass two more stitches around the tube and through the cornu to close the V, control the bleeding, and fasten the tube to the outside of the closed cornu.

526 Marquam Building.

BIOGRAPHICAL SKETCH OF MICHAELIS, THE PIONEER WORKER ON NERVE-REGENERATION.

By L. PIERCE CLARK, M.D.,

NEW YORK.

NEUROLOGIST, RANDALL'S ISLAND HOSPITALS; CONSULTING NEUROLOGIST, MANHATTAN STATE HOSPITAL AND CRAIG COLONY FOR EPILEPTICS.

While the history of our knowledge of nerve-regeneration is very ancient—the fact was known and commented upon by Galen, and even Hippocrates—yet the modern aspect of the subject is supposed to have been original with Cruikshank in 1776. However, the first carefully published experiments were brought out by Michaelis in 1785. Every authentic review of nerve-regeneration repeatedly cites Michaelis as a pioneer in this field of neurological surgery. No one, as far as I am aware, has stated where and when Michaelis did his experiments. I therefore undertake to clear up this point in historical research. The data at hand show that Michaelis did his work here in New York city during the closing days of the Revolution (1781-1783). I have been at considerable pains to verify this fact, and also to collect from collateral sources (French and German) all the data concerning Michaelis' somewhat varied and peripatetic career from Göttingen to Paris, to London, and thence as staff surgeon of the Second Hessian contingent to New York city, and finally to Germany again. Inasmuch as neurological surgery has recently been so active in the clinical field of nerve anastomosis as a treatment of a variety of peripheral palsies, especially so here in New York, it may not be without interest for us to know more of the man who first published authentic data proving structural and functional nerve-regeneration in reunited nerves. Assuming this to be the case I take pleasure in presenting here a short biographical sketch of Michaelis, and append thereto a short abstract of his experimental work on peripheral nerves and the deduction he drew from it.

Michaelis was the son of John David Michaelis, the distinguished Orientalist and Biblical scholar, and a cousin of the no less renowned Gustav Adolf Michaelis, the obstetrician of Keil. Christian Friedrich Michaelis, the distinguished German surgeon and anatomist of our sketch, was born in Göttingen in 1754 and graduated in medicine in Strasburg in 1776. His inaugural dissertation became famous, its subject being "Croup and Its Treatment by Tracheotomy." It was so well thought of that it was reprinted in France thirty-five years later.

Michaelis began practice in Paris, but removed later to London, where he became well known to the leading medical men. This is evidenced by a letter which he wrote for Richter's "Chirurgisches Bibliothek" at an indeterminate date, probably between 1779 and 1781. He met Cruikshank and saw his preparations of nerve-regeneration. Evidently he was much more sanguine as to the possibilities in this field than either Cruikshank or his preceptor, Hunter. It should be noted that Cruikshank's experiments were not only done on the vagi, but the results were not published until many years later, contrary to the usually accepted belief that it appeared in 1779.

When the British decided to send another corps of Hessians to reinforce their American army toward the close of the Revolutionary War, Michaelis received the appointment of staff surgeon. He must have reached New York at very nearly the time of Cornwallis' surrender, so that he could do no more than remain in that city until its final evacuation by the British. During these two years he made the most of his opportunities by entering private practice in the city.

In a letter in Richter's "Chirurgisches Bibliothek," sent to Göttingen during this period, he relates a number of clinical cases and discusses the work of the leading local practitioners, for all of whom he has a good word, which, in the case of Bailey, the surgeon, and Bard—who later became Washington's personal physician—amounted to admiration. In this letter he does not speak of the subject of nerve-regeneration, but states in his pamphlet that the work was done in America during these years, and therefore necessarily in New York. Neither does he in his report of the experiments make the slightest allusion to local places or names. Hence it is quite likely that his work was, for some reason or other, conducted with secrecy.

After the evacuation of New York he returned to Europe, reaching Germany during 1783. He was at once made professor of anatomy and practical medicine at Cassel and performed one experiment there, evidently to complete his work which had, perhaps, been interrupted at his departure from New York.

In 1785, his work having been finished, the report appeared in the form of a pamphlet published as a letter to the famous Dutch physician, Peter Camper. Its title was "Ueber Regeneration der Nerven." He had become aware of the experiments of some of his contemporaries and states that his own results had thereby been largely confirmed. He seems never to have returned to this line of research, although during ensuing years his results were widely disputed.

In 1786 he took the chair of anatomy at Marburg and maintained his connection with this university until his death, in 1814. Of numerous writings published during this period the best known probably is that in which he advocates the treatment of club-foot by tenotomy of the Achilles tendon.

Experiments Performed in New York in 1782-1783.—Michaelis' experiments may be given in abstract, just as they are reported in the original. To these may, then, be appended some further comments and conclusions of the author.

1. Dog.—Pieces three-fourths of an inch and one and one-half inches respectively, taken from the large crural nerves. The breach was filled with cellular tissue. While the lower stump became atrophic, the upper one swelled. No paralysis resulted. Other experiments gave the same results. The author next reports a series of experiments on the phrenics, but returned again to the crural nerves (see Exp. vi.). Further, a dog (Exp. vii.) which had been used at first for experiments on the phrenic was later subjected to excision of portions of the large crurals. Regeneration seemed to have occurred, as judged by the criterion that irritation of the nerve, either above, below, or at the site of the excision, called forth pain and convulsions.

2. In the same dog the phrenics were divided at the neck. The ends grew together, but without restoration of function. Later the entire nerve was excised and the callus examined. The lower nerve segment came away from it with but slight traction.

3. A piece an inch long was excised from the phrenic of a dog. Ten days later the gap was filled, but without return of function. The bridge entirely resembled nerve tissue, save in certain matters of color and thickness. The lower segment of nerve, however, was readily pulled out of the callus. The latter could be split like nerve tissue. Some nervous fibrils seemed to have grown into the callus, or bridge, without any real regeneration.

4. Dog.—One and a half inches cut from phrenic. Symptoms due to intervention subsided. One month

later nerve examined and bridge seemed to represent a true regeneration. Three months before the crural nerve of the same dog had been divided, with resulting complete regeneration.

5. Dog's phrenics divided. Eight weeks later complete restoration evident.

6. Pieces three-fourths of an inch long excised from large crural nerve of dog. Ten days later anatomical union, but atrophy of lower segment. Nerve had been excised between two ligatures.

7. Piece one inch long excised from right phrenic of a dog. Symptoms subsided. One month later whole phrenic dissected out. Complete regeneration, but bridge a little thinner than normal, and of a different color. That function was preserved was shown by the fact that irritation of any portion of the nerve, including bridge and lower segment, caused spasm of the diaphragm. The opposite phrenic was divided without any bad consequences, and regeneration of this nerve soon occurred without the agency of blood extravasation, although the severed ends were nearly an inch apart. The bridge formed appeared to be nearly like normal nerve tissue. The specimen was presented to Professor Blumenbach.

Division of the regenerated right phrenic now led at once to the animal's death. These crucial experiments appeared to show, beyond doubt, that regeneration had occurred.

Michaelis' Views on the Subject of Nerve-Regeneration.—The author states that as a practising surgeon he had become a firm believer, from clinical evidence, that complete restoration of sensation and motion could occur after injury to main nerve trunks. As examples he mentions complete reunion of severed fingers, gunshot wounds involving the arm, and the regeneration which has followed division of the infraorbital nerve for neuralgia.

Cruikshank's pioneer experimental work was left incomplete, and the author independently developed the idea of bringing research in this direction to a definite conclusion.

The experiments just cited did not comprise all of his work. He speaks incidentally of a series of negative results in rabbits (nerves not stated), and makes a first division, which is limited to absolutely negative findings—not the least evidence of regeneration—even under favorable conditions.

In a second class of cases failure of divided nerves to regenerate is due to "poor anatomical conditions."

Finally there is a third class of cases in which true regeneration appears to occur, both anatomically and physiologically. Traction on the nerves does not cause the segments to come apart. The regenerated substance does not represent anything but nerve tissue, homogenous with the nerve proper, but only about half as thick. Such a regenerated nerve could be split through the bridge without any separation.

In these positive results true regeneration was shown to occur after excision of one or two inches of nerve. Conversely, in some negative cases the nerve was simply divided.

The author's observation period seems to have been short—from ten days up to twenty or more. Reunion in a few hours or days he would not regard as possible. That he did not follow up his cases for weeks or months was probably due to lack of opportunity. But he seems to have been satisfied that if reunion did not occur within a reasonably short interval—say several weeks—the result must be regarded as negative.

The Mechanism and Treatment of the Attack in Spasmodic Asthma.—According to A. Morison the most prominent objective feature of an asthmatic attack is that in spite of violent efforts on the part of the patient to breathe, the respiratory results are abortive. The chest is almost motionless. One result of these straining efforts is a permanent distention of the chest. It is the amount of air changed at each breath and not the mere amount shut up in the lungs that counts in oxygenation and so relieves the demand of breathing. Much of the wheezing of expiration is laryngeal, though there may be some spasm of the bronchial muscles. In a condition of persistent inspiration and pulmonary inflation, it is quite probable that the obstacle to the egress of air may be largely, if not wholly, relative, unless tumefaction of the mucous lining of the tubes causes in addition actual narrowing. Such a condition of pulmonary inflation, however brought about, if at all protracted, necessarily implies dextrocardial repletion and the small pulse of a depleted left heart which is so characteristic of spasmodic asthma, for normal expiration is necessary to repletion of the systemic vessels. A true spasmodic asthma may also be superadded to a primary bronchitis. In such a case there is also inflammatory narrowing of the bronchi from tumefaction. Concerning treatment, advocacy is made of placing the hands on the patient's chest and making coincident with his expiration a squeezing movement so as to assist in emptying the chest. The author finds this maneuver a great relief to the dyspnea. Artificial expiration, then, is the proper name to give the method. Of course the disease should always be treated along conventional lines so far as the removal of underlying causes, neurotic factors, etc., is concerned. Naturally the procedure he advises is easier in young persons with greater rib elasticity, but even in old people with stiffened chests he has found compression by one hand over the thorax and the other over the epigastrium, lower ribs, or preferably over the right hypochondrio-epigastric region, procure relief from the thoracic anxiety attending preponderantly inspiratory fixation of the chest.—*The Lancet.*

Ivy Poisoning.—E. S. McKee has found that considerable relief is afforded in this condition by the use of lead and opium wash, but more prolonged comfort is obtained by dusting the whole body with rice powder. Comfort may also be secured by the application of a thick lather of laundry soap. For stopping the burning and itching and checking the spread of the disease, a useful mixture is compounded as follows: alcohol, 53., distilled water, 47., lead acetate, enough to make a saturated solution. For the nervous symptoms, thirty-grain doses of bromide of sodium with two drops of Fowler's solution to each dose may be given four to six times a day. To protect the desquamated areas and aid the growth of new skin applications of olive oil and lanolin, saturated solutions of iodide of potassium, tartar emetic, and sodium bicarbonate, weak carbolic acid solutions, and thymol iodide in powder or ointment, are all useful. When one has been exposed to the poison it is advisable to wash the parts several times with dilute alcohol.—*The Therapeutic Record.*

Poisonous and Fatal Action of Camphor.—Happich says that the occurrence of several deaths after subcutaneous injections of camphor led him to investigate the subject. Camphor in the body combines with glycuronic acid to form the inactive camphoglycuronic acid, hence the injection of camphor is inadvisable in patients who are deficient in glycuronic acid or the materials for producing it; that is, glucose and oxygen. Caution is therefore necessary in using camphor with patients having insufficient carbohydrate metabolism and who are cachetic, poorly nourished, have been poisoned by chloral hydrate, or have severe diabetes. Patients in whom oxidation is deficient, who have been poisoned by CO_2, who have grave valvular lesions, double pneumonia, eclampsia, or severe sepsis, also are predisposed to the toxic action of the drug.—*Zentralblatt für Gynäkologie.*

New York, March 17, 1906.

OLDER VIEWS IN REGARD TO YELLOW FEVER.

FEW diseases have in the course of their history given rise to more acrimonious disputes regarding causation, means of transmission, treatment, and prophylaxis, not only between members of the medical profession, but also among the laity, than has been the case with yellow fever. Leaving out of all account the differences of opinion regarding the causative agent and the quarantine squabbles which have occurred during comparatively recent years, it is interesting to recall the controversy between Benjamin Rush and his pupils, who, for a time at least, insisted on the contagiousness of the disease, and certain more enlightened observers who were of the opposite opinion and realized, albeit somewhat dimly, that some other unknown factor had still to be reckoned with in the transmission of the disease. Rush himself indeed, eminent as he was, was subjected to much vituperation by his townsmen because he asserted that yellow fever was not an imported pestilence, but had arisen in Philadelphia as the result of bad sanitary conditions. Among those who at about this time opposed the view that yellow fever was a contagious disease were a number of Baltimore physicians whose experience was rather different from that of their Philadelphia colleagues, and led them, in some instances, to the equally mistaken notion that quarantines were altogether useless.

In an address delivered before the Alumni Association of the University of Maryland on January 25, 1906 (*Old Maryland*, February, 1906), Dr. James Carroll, in discussing the various yellow fever epidemics in Baltimore, pointed out with what acumen some of the physicians of over a century ago foreshadowed conclusions concerning the nature of yellow fever that, though long disputed, we now know are true. Dr. Nathaniel Potter, a former pupil of Dr. Rush, and afterward the first professor of the Theory and Practice of Medicine in the University of Maryland, held in 1793 that yellow fever was not contagious, though according to his own statement he at that time believed he was the only person in America who held that opinion; and in 1797 Rush's contention was publicly attacked by Dr. John B. Davidge, the first professor of surgery and obstetrics in the same school. A striking observation is that recorded by Dr. Drysdale in the course of the epidemic of 1794 to the effect that "Locusts were not more numerous during the reign of Pharaoh than *mosquitos through the last few months;* yet these insects were very rare only a few years past when a far greater portion of Baltimore was a marsh." Dr. Davidge, in speaking of the subsequent course of the disease in patients removed from the low-lying districts along the water front to the higher ground of the city proper, says that the infectiousness of those who succumbed died with them, while "from those who recovered, all mischief and supposed contagion evanesced into empty air, which bore it to the pages of medical writers, and not to the bodies of healthy attendants. This was the result in 1794 and 1797." Dr. David M. Reese, in writing of the epidemic of 1819, pointed out the suggestive fact that persons visiting a certain infected district along the shore contracted the disease if they went at night, but not if they were there only in the daytime, and physicians who attended patients throughout the epidemic remained exempt, unless they happened to enter the district at night. This accords perfectly with the mosquito theory and the twilight habits of the stegomyia, and Dr. Carroll says that it is also in harmony with the experience of the American troops near Havana, who remained free from the disease if they visited the city only during the morning and early afternoon.

Dr. Carroll summarizes as follows the evidence collected by those early observers which could be used to support the mosquito theory to-day. Firstly, they recorded the presence of an unusually large number of mosquitos; secondly, they observed that the infection was localized in the low, wet districts near the river and shipping; thirdly, they noted that the infection was contracted mostly at night; fourthly, they showed that in the higher and drier ground of the city proper the disease was absolutely noncontagious; fifthly, they reported that the disease traveled in the direction of the prevailing winds, when these were strong and blew in one direction; and sixthly, they were familiar with the fact that yellow fever was most apt to prevail when the mean temperature was high, and they knew perfectly well that the disease was stamped out by the frost. To this we can add nothing more than the direct implication of the mosquito. Their mistake, however, lay in the fact that while they recognized that the disease was not contagious they did not realize that it could be imported, and they therefore protested against the quarantines that were instituted in the cities where the contagion theory was held. Dr. Carroll has provided an interesting retrospect of the views of these sagacious Baltimoreans, whose observations form an important chapter in a tale that, though apparently drawing near its close, is as yet far from complete.

THE PLACING-OUT SYSTEM FOR FOUNDLINGS AND WAIFS IN ENGLAND.

THE placing-out system for foundlings and waifs has been in vogue in the United States for some considerable time. It was first introduced in Massachusetts and in Pennsylvania, where its adoption was attended with great success. Of course, the fact has been known for long by medical men that when infants are massed together in one building and fed largely by artificial means, the resultant death-rate among them is appalling. Perhaps the

Foundling's Hospital at Randall's Island was the most notorious instance in point of truth of this statement. The report of the Committee of Inspection dealing with this institution, published in December, 1897, showed that of 366 children under the age of six months admitted to Randall's Island Hospital during the year 1896, only twelve were alive on April 15, 1897—a death-rate of more than 96 per cent. The matter was fully discussed editorially in the MEDICAL RECORD at the time, and it will be remembered that this deplorable state of affairs so aroused public sentiment that it was resolved to initiate a reform in the methods of management. Accordingly, the decision was arrived at to adopt the placing-out system. From Randall's Island the infants were removed to carefully-selected homes in the country. The system was put into practice in New York in the early part of 1898, and proved so satisfactory that the mortality rate fell from 55.9 per cent. in 1899 to 18.9 per cent. in the year ending March, 1906, a practical demonstration indeed that foundling hospitals are strongly contraindicated for infants.

In England the late Dr. Barnardo, the founder and organizer of the world-renowned homes known by his name, was the inaugurator of the placing-out system. The Barnardo scheme of dealing with the waifs and strays which fall within its scope is not confined to any one method, but embraces many methods. Roughly speaking, the statement may be made that infants are boarded out, as this mode of bringing up children under five or six years of age has been found the best. At the close of the year 1904 the Barnardo Association had 243 boarding centers, in which were placed 3,967 boys and girls. Great care is taken to choose suitable homes, and constant supervision is exercised over the children. Before a child is allowed to enter a cottage home one of the Sisters connected with the Association inspects the home, to ascertain that the accommodation is sufficient, and that the sanitary arrangements generally are satisfactory. A local committee is appointed, whose duty it is to take a certain number of homes under its supervision, and members of this committee constantly visit the children. The Association likewise employs its own visitors, persons of experience, including trained nurses, who spend their time in inspecting the homes and in taking note of the progress of the children placed in them. The boarders attend the village schools, and in all respects lead the life of the village children. It is claimed for the boarding-out system that it is beneficial in every way. It would seem reasonable to suppose that it must be healthier than living in an institution, and the assertion made by its advocates that it tends to counteract to a certain extent the present-day trend of the country into the towns is also sufficiently credible. In short, the system may aid, in some degree, in solving the problem of how to deal effectively with the poor and neglected children of our large cities.

London's Ambulance Service.—Horse ambulances are still a "crying need" in London. The other day a man, taken seriously ill in the street, had to wait where he was four hours before a conveyance could be obtained to take him to a hospital.

ACETANILID.

THERE is a curious feature in the crusade against proprietary remedies, initiated by one of the State journals and recently taken up with the proverbial zeal of the convert by the *Journal of the American Medical Association*, which many honest souls cannot quite understand. Up to a year or so ago this last-named journal was a most flagrant sinner in the matter of "unethical" advertisements, and even yet its baptismal robe is a little spotty; but so violent has it now become in its onslaught on the "proprietaries" that there is no room for doubt, in the minds of the unthinking, that its conversion is sincere. One of the first moves in the war against what are called, with verbal waste, "secret" nostrums was the appointment of a Council on Pharmacy whose task it is to analyze all the "proprietaries" and to prepare a sort of unofficial pharmacopeia for the guidance of practitioners. The Council has been rather inactive of late, so far as its published reports are concerned, but it was very busy at first, and soon after its creation published a series of analyses of various mixtures said to contain acetanilid as their active ingredient. In this *index expurgatorius* were included not only the preparations advertised solely to the profession but also a number of "headache powders," frankly classed as "patent medicines" and advertised in the lay press and on billboards, fences, and conveniently shaped rocks throughout the country.

So far, so good. The ignorant use by the laity of powders or mixtures containing a powerful drug is pernicious, whether the drug is cocaine, opium, alcohol, or acetanilid; and the same is true of the prescribing of secret preparations by physicians. But immediately after the publication of this report in the *Journal of the American Medical Association* there appeared in the same journal a series of articles treating of the dangers of acetanilid and recounting cases of untoward effects following the injudicious use of the same. Why this special attack should have been made on acetanilid, instead of on opium or cocaine, both of which are probably more extensively, and certainly more injuriously, used in the so-called "secret nostrums" than acetanilid, we are able only to conjecture. Acetanilid is a valuable and ethical drug, admitted ten years ago to the United States Pharmacopeia and retained in the recent revision, and very much cheaper than its chief rival among the synthetic analgesics and antipyretics, the sale of which has doubtless been increased by this attack on the pharmacopeial preparation.

We are at one with the Chicago journal in decrying the use of mixtures containing acetanilid or any other drug, the exact proportion of the ingredients of which is kept secret by the manufacturers. The physician cannot prescribe intelligently unless he knows what he is prescribing—that is as undeniable as any of the truisms of the code of ethics. But what that has to do with the physiological and therapeutic effects of acetanilid is a puzzler for the uninitiated. The Committee of Revision of the United States Pharmacopeia not only retained acetanilid, but judged it such a useful member of the official family that it added an official mixture—pulvis acetanilidi compositus—thereby not only setting the seal

of approval upon this drug, but emphasizing the general opinion that it is one of undoubted utility and therapeutic value. It is liable to abuse, like any other powerful remedy, but even its continued exhibition is less often followed by the establishment of an enslaving habit than is that of many other drugs. Its use in any form, whether the pharmacopeial powder or one of the secret headache "cures," by the laity, except on a physician's prescription, cannot be too strongly condemned; but, intelligently prescribed to meet definite indications, it is an excellent remedy, and the Committee of Revision acted wisely in retaining it among the official drugs of the United States Pharmacopeia, notwithstanding the opposition of our highly esteemed, though overzealous, contemporary. One undoubted advantage which it possesses is that it is so very cheap that there is little temptation for the dishonest druggist to adulterate it.

Strychnine and Chloroform.

Strychnine is known to increase the irritability of the brain and spinal cord, it stimulates the vasomotor centers, and as a result produces an increase in the blood pressure. The tetanus resulting from strychnine poisoning has also been shown to bring about finally a paralysis of these centers, to which fact may probably be ascribed the fatal issue in such cases. Chloroform, on the other hand, diminishes the irritability of the central nervous system, it also inhibits the action of strychnine on the vasomotor centers. It would seem rational to assume that the effect of doses of strychnine approaching those of toxic dimensions which have been injected into an animal organism, might at least be weakened by the administration of chloroform. This interesting proposition has been made the subject of a series of experimental observations by Hugo Meier (*Deutsche Aerzte Zeitung*, No. 3, 1906) on mice which had been chloroformed. These were given toxic doses of strychnine (0.5 mg. per 100 gm. of body weight) and in practically every instance similar phenomena were observed. Aside from a single tetanic contraction which came on some time after the injection, there was no actual tetanus produced, and this state was succeeded by a condition which closely resembled that seen in curarized animals. Some of these animals died, others survived the experiments. Meier accounts for this phenomenon by assuming that chloroform merely inhibits or rather weakens the stimulating effects produced on the central nervous system by the strychnine, whereas the paralyzing action of the alkaloid on the motor nerve-endings is not thus affected and this is the only one which comes into play. The use of chloroform as a therapeutic resource in strychnine poisoning need hardly be considered, however, for the physiological action of the chloroform must be induced at the same time as that of the strychnine. As a matter of fact, in this as well as in all other forms of poisoning, relief is usually not sought until toxic symptoms have become evident, and in this event chloroform can no longer be of service. It seems more rational to consider the author's suggestion to administer strychnine with this end in view in cases of chloroform poisoning. The proposition contained in this preliminary communication is of considerable interest and it is to be hoped that an opportunity will be afforded to the author to put his theories to a practical test. It will require considerable courage and assurance, however, to administer to a patient on the verge of collapse from chloroform a dose of strychnine such as that referred to, which would ordinarily be regarded as fatal.

Gynecological Examinations by a New Method.

There is a certain class of gynecological cases in which for various reasons a bimanual examination may be rendered difficult or impossible, and very often it is necessary to anesthetize the patient before a satisfactory diagnosis can be made. This method of procedure is of course open to many objections, and aside from the natural tendency to avoid narcosis unless an absolute necessity for the same exists, anesthesia suppresses a symptom of great diagnostic importance, namely, localized pain. Thus a patient may refer her pains to the ovarian region, and when on examination under ether an enlarged ovary is found, the trouble is naturally attributed to this source, although in fact it may be due to a lesion in the pelvic cellular tissue or the peritoneum. The exact site could have been elicited only when the patient was entirely conscious and able to respond to the touch of the examining finger; during anesthesia no such distinction could be drawn. A mutilating operation of greater or less extent may even be done without producing any relief from the original disturbances. To obviate these shortcomings in gynecological methods of examination, Profanter (*Wiener klinische Wochenschrift*, No. 6, 1905) suggests a novel procedure which he has found eminently satisfactory. This requires the patient to assume a half-reclining position in a bathtub filled with warm water. It is found that the tense abdominal muscles are immediately relaxed, and as soon as the water is permitted to enter the vagina the latter is distended and readily permits the introduction of the examining finger. Another beneficial effect of the bath method consists in the disappearance of all local sensitiveness, so that the necessary manipulations can be done without causing pain or producing resistance. Under ordinary circumstances the method may be objected to by the patient as entailing an undue amount of exposure, and by the physician as being productive of considerable discomfort in its execution, but the writer promises a suitable apparatus at an early date in which these sources of objection will be entirely overcome.

News of the Week.

For National Quarantine.—In spite of some opposition on the ground of interference with State rights, the House Committee on Interstate and Foreign Commerce has agreed to make a favorable report on a committee substitute for the Williams bill to extend Federal control of quarantines. According to the plan proposed the Secretary of the Treasury is placed in direct control of quarantine, and is to administer it through the Public Health and Marine Hospital Service. The bill carries an appropriation of $500,000.

Meningitis at the Newport Naval Station.—Two more deaths from cerebrospinal fever among the apprentices at the Newport Naval Station have been reported. One of the patients had been ill for three months, the other for only a few days.

Tuberculosis Among Federal Employees.—President Roosevelt on March 8 issued an order to the heads of all departments giving them explicit in-

structions in regard to their duties in controlling tuberculosis among their employees. The order provides for the distribution of circulars containing instructions on the prophylaxis of the disease, for the medical examination of persons suspected of being tuberculous, and for a general investigation of the sanitary conditions existing in all the public departments and workshops, to be conducted under the direction of the Surgeon General of the Army, the Surgeon General of the Navy, and the Surgeon General of the Public Health and Marine Hospital Service. The order is issued in accordance with the report and recommendations of the committee appointed by Executive order of December, 1905, to prepare a plan for the prevention of tuberculosis in the Government offices and workshops.

Transfer of the Newberry Library to the John Crerar Library.—Arrangements have been completed for the transfer of the medical department of the Newberry Library, including the Senn collection on medical history, to the ownership and management of the John Crerar Library. This has been done partly because the natural relation of these books to the chosen field of the John Crerar Library and the lack of such relations to that of the Newberry Library make the transfer in many ways mutually advantageous, and partly because the medical profession of Chicago has urged strongly the desirability of a more central location.

The Patent Medicine Evil will be discussed by Mr. Norman Hapgood, editor of *Collier's Weekly*, on Sunday afternoon, March 18, at 3.30 o'clock, in the Majestic Theatre. The meeting is under the auspices of the West Side Young Men's Christian Association.

A Field Hospital for the New York National Guard.—The New York National Guard is to have a field hospital, to be attached to headquarters and intended to be used in caring for the sick and wounded when the guard is in camp or performing riot duty, or on other service. The field hospital will conform to army methods as far as the State service will permit, and will not in any way interfere with the present regimental hospital corps. All sick men in care of the regimental hospital who may not have recovered after twenty-four hours can be turned over to the field hospital, as is done in the army. The field hospital will then be responsible for the sick or injured, and if men are unable to be removed to a permanent city hospital they will be cared for in the field until recovered. It is proposed to have the force consist of four officers and forty-six enlisted men. The commanding officer will be a surgeon with the rank of major, and the other commissioned officers will be three assistant surgeons with the rank of captain. Dr. William S. Terriberry of the Twelfth Regiment, who served as a medical officer in the war with Spain, will, it is understood, command the new field hospital, and will be assisted by Dr. William E. Butler of the Twenty-third Regiment and Dr. T. A. Neal, late of the Seventh Regiment. The fourth officer has not yet been selected.

Auto Speeding by Physicians.—As a result of the recent arrest of the chauffeur of a physician who was exceeding the speed limit in responding to an urgent call, the suggestion has been made that the Police Department issue a card bearing a red cross, to be displayed by physicians or their chauffeurs in automobiles, which shall be accepted by the police as a license to exceed the speed limit in visiting extremely urgent cases of illness. We trust the Police Department will not accept any such suggestion. No case is so urgent as to warrant exposing a city full of children, the aged, and the infirm to the danger of fatal injury by a speeding motor car.

Paid Internes at Bellevue Hospital.— On February 28 the Civil Service Commission granted authority to the trustees of Bellevue Hospital to engage four physicians, at a salary of $600 a year, to assist the internes in the reception wards. It is proposed to appoint the retiring house physicians to these positions.

A Law to Compel the Publication of Formulæ.—Assemblyman Wainwright and Senator Stevens have introduced into both houses of the New York Legislature a bill entitled, "An act to amend the public health law by providing for the proper labeling of proprietary and other medicinal preparations containing alcohol or narcotic or other powerful potent drugs, and for the inspection, analysis, and regulation of the manufacture and sale of the same." The bill was presented to the Legislature at the instance of the New York State General Committee for Safeguarding the Sale of Narcotics, of which Mr. William A. Jenner is chairman, and Mr. William T. Wardwell and Dr. A. Jacobi, vice-chairmen. The bill prohibits the manufacture and sale of medicinal preparations containing alcohol or other narcotic or poisonous drugs unless the formula, both qualitative and quantitative, is printed on the label in plain English. Analyses of these preparations are to be made from time to time by the State Department of Health, either on its own initiative or on the complaint of any citizen, to determine whether the actual ingredients are as stated on the label. Violation of the law is made a misdemeanor punishable by fine or imprisonment, or both, in a criminal proceeding, and providing for a forfeiture of $50 to the State Department of Health in all places outside the cities of New York and Buffalo, and to the municipal Health Department in those two cities. The law does not apply to preparations intended solely for external use, or to the dispensing of compounds on prescriptions by legally authorized physicians, dentists, or veterinarians, nor to preparations listed in the Pharmacopeia of the United States unless sold under proprietary name or trademark.

Dr. Palmer Findley of Chicago has accepted the Chair of Gynecology in the College of Medicine in the University of Nebraska, Omaha.

Chicago Ophthalmological Society.—At the annual meeting of this society, recently held, Dr. George F. Fisk was elected president, and Dr. E. V. L. Brown secretary and treasurer.

Harvey Society Lectures.—The thirteenth lecture in the Harvey Society Course will be delivered by Professor W. H. Howell of Johns Hopkins University at the New York Academy of Medicine on Saturday evening, March 17, at 8:30 P.M. Subject, "The Cause of the Heart Beat." This will be the last lecture of the series.

Dr. L. Duncan Bulkley will give four special lectures at the New York Skin and Cancer Hospital, Second Avenue and 19th Street, on "The Principles and Application of Local Treatment of Diseases of the Skin," on Wednesday afternoons, March 21 and 28, and April 4 and 11. Dr. William Seaman Bainbridge will give a clinical lecture on "Malignant and Non-Malignant Growths," on Wednesday, April 18, in the Out-Patients Hall of the hospital. All of these will be at 4:15 o'clock and will be free to the medical profession.

Medical Exhibition in London.—An exhibition of instruments, pharmaceutical supplies, and other products likely to be of interest to medical men is to be held in London, October 1 to 5, 1906. The Secretary and Manager is A. Normon Flack, "British and Colonial Druggist" Offices, 44 Bishopsgate Without, London, E. C.

Medical Society of the Missouri Valley.—The next meeting of this society will be held at St. Joseph, March 22 and 23. An excursion to Excelsior Springs has been planned as part of the program.

To Improve the Hygienic Conditions of the Philadelphia Chinatown.—Dr. A. C. Abbott, President of the Philadelphia Bureau of Health, after personal inspection, will take steps to improve the hygienic conditions in that portion of the city known as Chinatown. In some houses small rooms with low ceilings, and occupied for sleeping purposes by several persons, were found unprovided with windows, and many other violations of sanitary requirements were discovered.

Dr. D. J. DeJarnette, second assistant physician of the Western State Hospital at Staunton, Va., has been elected superintendent of that institution to succeed the late Dr. Benjamin Blackford.

Otisville Tuberculosis Sanatorium. — In order to hasten the work on certain improvements desired the Board of Health has asked for $20,000 to spend on the Otisville Tuberculosis Sanatorium without public letting. The regular routine requires advertising of contracts far in advance and then the publication of bids. If the Health Department has to follow this routine, the improvements and additions cannot be made in time for patients to reap the benefits of them this summer.

Dr. M. V. Mabon, President of the State Lunacy Commission, is going to resign to take charge of the Manhattan State Hospital, on Ward's Island, New York.

The Smoke Nuisance.—At a meeting of the Board of Health, on March 8, it was decided to reenact an old ordinance requiring the use of smoke consumers. This was omitted when the Sanitary Code was revised under the Low administration, but it is to be reinstated as soon as possible. The police Bureau of Boiler Inspection, which issues licenses, will also examine firemen and engineers in regard to taking care of superfluous smoke. Greater activity in securing the punishment of offenders is also promised. In view of the threatened strike of the anthracite coal miners, and the consequent increased consumption of bituminous coal in this city, the activity of the Health Department in this direction is very timely.

The Tri-State Medical Association of North Carolina, South Carolina, and Virginia, at its meeting, held at White Stone Springs, S. C., on February 27 and 28, elected the following officers: *President*, Dr. R. E. Hughes, South Carolina; *Vice-Presidents*, Dr. I. M. Taylor, North Carolina, Dr. J. H. Hayne, South Carolina, Dr. W. E. Driver, Virginia; *Secretary and Treasurer*, Dr. J. H. Way, North Carolina.

More "Euthanasia" Folly.—The question of legalized murder is again to the fore—in Iowa this time, where, on March 10, a bill was presented in the lower house of the legislature providing for the killing of those suffering from painful disorders certain to end in death, and also intended to prevent the rearing of hideously deformed or hopelessly idiotic children. At least three physicians and the County coroner must unanimously agree and participate in the act, and then it must be with the consent of the nearest relative, and, if practicable, of the patient himself. Any deviation from this requirement constitutes murder and subjects the offender to the penalty of murder. The bill provides a heavy fine for any physician who shirks his duty under this law, and also prescribes the usual penalty for first degree murder for any abuse of it.

A "Tiny Tim" Cot, named after the little personage of that name who figures in Dickens' "Christmas Carol," has been endowed by the Manhattan Dickens Fellowship in the Home for Crippled Children at Bath Beach, to be run by the Children's Aid Society.

Hospital Transfers of Dying Patients.—At a meeting of the Manhattan Board of Coroners, held on March 9, a resolution was adopted condemning the alleged practice of transferring dying patients from the large private hospitals to Bellevue Hospital and other charitable institutions. The incentive to this action was the death of a patient from heart disease, while being taken in an ambulance from a large private hospital to Bellevue.

Measles and Diphtheria.—The increasing morbidity from these two diseases has impelled Health Commissioner Darlington to issue an appeal to the people of greater New York asking them to take all precautions to prevent an epidemic, particularly by summoning a physician at the first sign of illness, and by a free use of antitoxin in a suspected diphtheria case. There were reported to the department, 6,310 cases of measles for last month, as against only 901 cases for February, 1905. March of 1904 was the record month for measles in New York, 7,000 cases being reported, but this month promises to beat the record.

Spitters Arrested.—In consequence of an acute exacerbation of activity on the part of the Health Department, thirteen men of all sorts and conditions were arrested in one day last week for spitting in forbidden places. Ten of the offenders had been captured in the lobbies of theaters, where no spitoons were provided, and on this ground they were, the next day, discharged without a fine; but three others, who had sinned on the platforms of the elevated railway, had to pay one dollar each. Spitting on the floors of cars and of ferry boats is not so common as it used to be, but there is still much room for improvement in this direction, and we hope that a permanent anti-spitting squad will now be detailed to purge public conveyances of this variety of germ disseminators.

Tonsillitis in Yonkers.—More than one thousand cases of follicular tonsillitis are said to have been under treatment in Yonkers at one time last week.

Obituary Notes.—Dr. Grove S. Beardsley of Syracuse, N. Y., a retired surgeon of the U. S. Navy, died on March 7, at Atlantic City. He was born in Verona, N. Y., in 1838, and was appointed assistant surgeon in 1861. He became medical director in 1891 and was transferred to the retired list in 1900.

Dr. Charles W. Townsend of New York City, died on March 6, at the age of thirty-seven years, of cerebral abscess.

Dr. Frank J. Freel, formerly of Brooklyn, died on March 9, at his home in Stony Creek, Conn., in his forty-eighth year. He was a graduate of the Long Island College Hospital, but had done little active professional work.

Dr. Charles A. Lindsley of New Haven, Conn., died of heart disease on March 9. He was born in Orange, N. Y., in 1826, and was graduated from Trinity College in 1849. Three years later he received his degree from the Yale Medical School, and in 1860 he was made professor of materia medica and therapeutics in the same institution, a position which he retained until the time of his death. He was largely instrumental in the formation of the State Board of Health in 1874, and for twenty-two years he served as its secretary and administrative head.

Dr. Elizabeth N. Bradley-Byström died at her home in Dobbs Ferry, N. Y., on March 9, at the age of 54 years. She was born in Chicago and was graduated in medicine with honors from the University of Paris in 1887, her thesis, defended with much skill against such men as Fournier, Robin, Pouchet, and Gautier, being on "Iodism." She practised for ten years in New York, and then went to Brooklyn, and finally to Dobbs Ferry. In 1892 she married Mr. Ernest Byström, the Swedish pianist.

Dr. Sanford W. Adams of Mount Vernon, N. Y., died on March 7, at the age of twenty-nine years. He was a graduate of the New York Post-graduate Hospital.

Dr. William Hill of Bloomington, Ill., died on March 1, at the age of seventy-seven years. During the past fifty years he was widely known of throughout central Illinois, and was for many years president of the McLean County Medical Society.

Dr. Joseph Torkington of Pawtucket, R. I., died on February 27, at the age of fifty-six years. Dr. Torkington was a native of Lancashire, Eng., but came to this country when a young man, and was graduated from Jefferson Medical College, Philadelphia in 1885. He returned to England where he practised for a short time, but soon came back to this country, and a few years ago located in Pawtucket.

Dr. John T. Cotton of Charleston, W. Va., died on March 3, after a lingering illness. He was born in 1819, and was a member of the first class of Marietta College, Marietta, O., which was graduated in 1838. He first practised at Ravenswood, W. Va., and in 1845 removed to Charleston, where he had resided ever since.

Dr. Elmer W. Heltman of Toledo, O., died on March 3, after an illness of six months, at the age of forty-four years. He was a graduate of the Toledo Medical College and had practised in Toledo for about fifteen years.

Dr. John O. F. Hill of Gravesend, L. I., died on February 27, at the age of forty-two years. He was a graduate of the Long Island College Hospital in the class of 1886, and since that time had practised in Gravesend.

Dr. B. W. Woodburn of Bremen, Ky., the oldest practitioner of Muhlenberg County, died on February 24, at the age of seventy-three years. He had practised medicine in Bremen for over fifty years.

Dr. George W. Williams of Farmington, Mo., died on March 2, at the age of eighty-seven years. Dr. Williams was one of the oldest practising physicians in Missouri, having been engaged in active work for more than sixty-five years.

D. Edward W. Derby, who had practised in New York City for over fifty years, died on March 10, at the age of seventy-seven years. He was a graduate of Williams College, and received his medical degree from the New York University Medical College, in 1853.

Dr. David Dorrington Richardson, chief resident physician in the department for males at the Pennsylvania State Hospital for the Insane, at Norristown, died suddenly on March 6, at the age of sixty-nine years. He was graduated from the medical department of the University of Pennsylvania, in the class of 1871. He was, for a number of years, chief physician to the Insane Department of the Philadelphia Hospital. Later he aided in the establishment of the Delaware Hospital for the Insane at Farnhurst, and he also organized the State Hosp tal for the Insane at Warren, Pa.

Correspondence.

OUR LONDON LETTER.

(From Our Special Correspondent.)

HOSPITALS, COLLEGES, AND THE UNIVERSITY—SUCCESS IN THE PROFESSION—INFUSION OF VIOLETS IN CANCER—SURGICAL TREATMENT OF CANCER OF UTERUS—FEEBLE-MINDED—OBITUARY NOTES.

London, February 23, 1906.

Yesterday University and Kings Colleges, the Middlesex, the Royal Ophthalmic, and two or three other hospitals held their annual meetings, and many appeals for funds have been prominently before the public for general expenses as well as for rebuildings and removals. Prince Francis of Teck presided as vice-president at the Middlesex Hospital, where the repairs have been very heavy and where money is further needed for the endowment of the school started by Mr. H. Morris with a donation of £1,000. After the meeting a visit was paid to the chapel of the hospital, which is unique among the London churches for its beautiful mosaics and marbles. During the week the Countess Bathhurst unveiled a window she had added in memory of her brother, the late Hon. Oliver Borthwick, who had been an active supporter of the hospital and worker on its Board of Management.

Lord Reay presided at University College at the last meeting under the old order, as the incorporation with the University of London is to be completed in September. He said although the college would lose to some extent independence, it was for the good of university education in London as a whole, and he was therefore glad that Kings College would follow their example. There seemed some doubt about the new project of a great college of technology, but he was convinced that unless all higher technological work was in the hands of the same authority, there would be overlapping, duplication, perhaps triplication, as in the past. If brought within the university on the same lines as this college, the new institution would be under the direction of the Senate on matters of university policy, but in all other respects would be free or self-governing. It was the privilege and duty of the university to coordinate the many agencies of the higher culture that abounded in London.

Sir F. Treves, as Lord Rector of the Aberdeen University, delivered his address yesterday, taking as his subject: "The Bases of Success as Illustrated in the Career of a Medical Man." He was disposed to believe there had been more heroes in this than any other calling, a heroism marked by self-sacrifice even to laying down life. It was common to say success in life depended on fortune, influence, social position, even genius. These were rather hindrances. The lives of eminent doctors demonstrated that unearned money counted for nothing in the struggle, so neither influence nor social position helped. He was no believer in luck, which meant only that a man was ready for an opportunity if it presented. The contention that success needed genius was also vain. A man who excused himself by saying he was no genius lacked more than he owned. Genius was an unstable thing, for the definitions of it were various. It seemed the outcome of a quickly-working brain, the machinery of which need not be elaborate so long as it was easily set in action. In a physician it might conduce to flippancy, diagnosis by instinct, and other phenomena suited to the charlatan. In a surgeon, it was a quality from the possession of which he might pray to be saved. Success in surgery was measured now not by the rapidity so useful in preanesthetic days, but by the duration of the recovery. Having disposed of these negligible qualifications, Sir Frederick passes on to state the factors which make for success. These he held were health, serviceable knowledge, sympathy, and honesty. Industry was presupposed, as one could not conceive of a moving millwheel without a stream.

For several months certain newspapers have reported at intervals that patients have made marvelous recoveries from supposed cancer under treatment by infusion of violet leaves. The hopes and fears of patients have induced their attendants to examine the facts. These have now been discussed by the Royal Medical and Chirurgical Society. At the meeting on February 13 a paper on the subject was read by Dr. Wm. Gordon, who nearly a year ago related in *The Lancet* a case of presumably malignant disease which disappeared during the treatment, and he has collected a number of cases so treated, some under his own observation. He is not so foolish as to talk of "cure" after a few months' observation, and is of course aware that disappearance of malignant disease is not unprecedented, but he thinks it desirable to inquire further into the effects of violets, and perhaps so to correct the misstatements of the newspapers. Dr. Gordon related at length four cases, two with all the appearance of cancerous growths, the only

doubt of their nature arising from their disappearance, but one of them recurred; a third case, with the microscopical and general appearance of cancer, greatly diminished in size, but only for a time; the fourth case he thought indicated that the treatment could act on cancerous tissue. Brief details of forty-three other cases were given. In most of the cases the infusion had been used both internally and externally. It was made of about fifty good-sized, freshly-picked, garden-grown violet leaves, with the stalks, to a pint of boiling water, infused for twelve hours and strained. Half of this green liquid was taken during the day, either at once or in divided doses. The other half was used for local applications according to the part diseased. The infusion had sometimes caused anorexia, diarrhea, temporary increase of pain, rash, shortness of breath, and faintness, but properly used, the drug was not dangerous. Dr. Gordon considers that although it would be utterly unjustifiable to advise this treatment as a substitute for possible operations, it is desirable to try it after operation, to ascertain if it can prevent recurrence, and also in inoperable cases, to determine whether it can cause disappearance of the growth, or bring it within the reach of operation, or alleviate symptoms.

Mr. Pearce Gould, vice-president, who was in the chair, remarked on the difficulties which beset the subject. A sharp distinction must be made between relief of symptoms and diminution of size of growth. Then the usual course of malignant disease was very uncertain. Nearly every case related in the paper could be paralleled by some which had undergone no treatment at all. Rapidity of growth varied in a remarkable manner; arrests were known to all; active scirrhus of the breast might atrophy. Of Dr. Gordon's cases, he doubted if the first were cancerous, no glands being enlarged, the distribution of the second was unusual, and the two raised the question of the possibility of a merely clinical diagnosis. In the third case, with a microscopical report, there were doubtful features. Actinomycosis had only lately been differentiated from cancer, and there may be other unrecognized conditions to cause confusion. He had tried the treatment at the Middlesex Hospital, but had no success to report. In one case of mammary cancer the growth diminished, and a sloughing ulcer which was also present cleaned up, but the improvement did not continue. Temporary relief was often met with under various treatments, and he would admit this sometimes might seem due to the violet infusion.

Dr. Norman Moore agreed almost entirely with Mr. Gould. Microscopical examination was not alone decisive. The relief of pain did not prove improvement. The cases related illustrated the natural course of the disease. He did not think the treatment of any value.

Dr. Blake said he had seen apparent disappearance of supposed internal cancer under hypnotism, and thought in many cases faith in a fresh remedy had some effect. In reply to a question, he admitted he had seen nothing of the kind in external cancer.

Mr. Faulder said palliative treatment was often useful. Inoperable cancer of the rectum might become operable after colotomy.

Dr. Dudgeon remarked that inflammatory conditions often simulated cancer.

Mr. Bowseman Jessett's inaugural address as president to the Gynecological Society was devoted to cancer of the uterus. He remarked that it is now more than twenty years since he first removed the organ, but his early cases were unsuccessful and he determined not to operate again unless in a case he considered highly favorable. Such a one he met in 1892, since when he has operated on over two hundred cases. At the cancer hospital only a small percentage of patients are seen early enough. If family doctors insisted on a vaginal examination in every case of discharge or irregularity, many lives might be spared. Sir Halliday Croom showed that malignant disease often begins after labor, and American physicians insist on the importance of periodical examination after delivery. Mr. Jessett went on to point out the difficulties which beset the early recognition of danger by patients and their attendants, and even when fear is entertained, the impossibility of a microscopic examination alone settling the diagnosis. He then said that his own investigations did not indicate that glandular infection was as frequent as supposed, and in this conclusion he was supported by other observers whose reports and figures he quoted.

As to operation, the great question to consider is in what cases it holds out a fair hope of benefit and possible cure. Here Mr. Jessett found English gynecologists more conservative than American or Continental, and evidently he agrees with his countrymen. Kroenig's heroic surgery in advanced cancer immovable even under narcosis, was noticed only to express the conviction that when the uterus is fixed and the ureters and bladder implicated, no operation can benefit the patient, though there may be cases on the border line in which it may be hoped to get beyond the disease, such as where the os was primarily affected and the disease has crept along the roof of the vagina just into the areolar tissue beneath.

Wertheim's paper at the Lincoln meeting last year (Report of British Medical Association in the MEDICAL RECORD, August 19, 1905) was pronounced a very valuable addition to our knowledge, and his results truly surprising, he having performed his formidable operation on two hundred and seventy cases, with a mortality of 15 to 18 per cent., and having lost only two out of his last thirty cases. Moreover, 60 to 70 per cent. have not recurred after four to five years. Notwithstanding these brilliant results, Mr. Jessett had only performed Wertheim's operation in three cases, and he opined it would be some time before British gynecologists adopted it.

As to the relative merits of vaginal and abdominal hysterectomy, the mortality seemed to be two or three times greater in the latter. In more than two hundred cases by the vaginal route, Mr. Jessett had only ten deaths, and of his last seventy-three cases only one died. Of one hundred and eighty of these done more than two years ago many had been lost sight of, but seventeen are now alive and well, three to twelve years after, and 20 per cent. were free from recurrence from two to five years.

When the fundus or body is attacked, the vaginal is the better operation, it having been established that no glandular infection takes place unless ulceration through the wall occurs. This was also the best course when the disease was limited to the os and vaginal portion of the uterus. But when extension up the cervical canal, infiltrating the cervix and possibly infecting the cellular tissue, has taken place, either the abdominal or combined operation might hold out the only hope. When the uterus is fixed and the ureters and bladder perhaps implicated, the cases were, Mr. Jessett said, better left rigidly alone.

The Royal Commission continues collecting opinions of various medical officers on the care and control of the feeble-minded. Dr. Pasmore of the Croydon Mental Hospital and the County Asylum stated as the result of his studies that 55.4 per cent. of cases of insanity have an insane history, fifty-five males and forty-five females, and there is a direct inheritance in 34 per cent. Where there is no history in the family, 46.2 per cent. are recoverable, but with insane history, only 28 per cent. In Croydon there had been an increase of insanity of 6 per cent. in the last five years. He recommended legislation giving power to control the property of defectives, dropping the term "asylum," adapting existing institutions for receiving defectives, compulsory removal from their homes and from workhouses of all idiots and defectives over sixteen, compulsory detention of habitual drunkards, schools for defectives, and registration in order to trace them afterward, state crêches under one central governing body.

Dr. Whiteside Hime advocated extra classes and finding interesting employment for defectives, releasing them from routine school attendance. He would have no classes for continuance of memory exercises, as in elementary schools. Criminally-disposed boys should be detained in an institution where they could be treated medically or educationally, as they needed. They should not be placed with imbeciles or defectives. Prison was not the place for juvenile criminals who suffered from mental perversion. The existence and degree of this was a matter for the medical expert, as was the treatment.

The chairman and ex-chairman of the Leeds special schools recommended that where the feeble-minded are detained in homes, segregation should be carried out, and as heredity was largely accountable, it was desirable to stop intermarrying among the feeble-minded.

A death has occurred under ethyl chloride, given for the extraction of four teeth. The patient was a clergyman of 67 years, and when three of his teeth were removed he suddenly expired. The deceased was suffering from fatty degeneration of the heart, and his death was attributed to syncope induced by the anesthetic.

The death is announced of the Rev. Canon Oakley Coles, L.D.S., who was dental surgeon to the Throat Hospital until 1886, when he entered the Church. In 1899 he was given a canonry at Canterbury. He was closely associated with Morell MacKenzie, whose sister he married, in the establishment and management of the Throat Hospital, and also in the directory of the *Medical Examiner*, which they conducted with vigor during its brief career. Mr. Coles wrote a volume on "Oral Deformities," of which he had much experience at the hospital. He was editor for a time of the *Monthly Review of Dental Surgery*, and dean of the National Dental Hospital.

Surgeon-General J. P. Walker, late of the Bengal army, who died on the 14th inst. in his eighty-sixth year, took his M.D., Aberdeen, in 1842, and his M.R.C.S., Eng., in 1844. The next year he went to India, and served throughout the mutiny, retiring in 1877 with the rank of surgeon-general. He was the senior member of the Indian medical service.

Dr. T. S. Odling, C.M.G., physician to the British legation in Persia, died on Saturday at Teheran.

OUR VIENNA LETTER.

STRIKE OF AUSTRIAN PHYSICIANS—OPERATION ON A DOUBLE MONSTROSITY—ABNORMAL ROTATION OF THE HEAD—SPIROCHETES IN A GINGIVAL CHANCRE—JACKSONIAN EPILEPSY—SPINAL INJECTIONS IN GENITOURINARY DISORDERS.

VIENNA, February 5, 1906.

SINCE the first of February a large proportion of the Austrian physicians, particularly the country and circuit practitioners, have been on strike. The causes of this movement depend on the inadequate compensation allowed by the government for vaccinations, the examination of foundlings, vagabonds, etc., and as in addition the authorities are not favorably disposed toward the profession, the strike was decided upon and carried out, thanks to the efficient organization. The sick do not suffer, however, as only services to the government are comprised in the boycott, and it is to be expected that the authorities will yield and concede suitable compensations to the physicians.

An interesting operation has been performed by Prof. Kukula of Prague on the two united sisters, Rosa and Josepha Blazek. Although the twins were united over a considerable area, the two bodies were quite independent, as is shown by the fact that one sister suffered from diseases which did not affect the other. Thus Rosa was subjected to an operation for stone in the bladder, which was successful, and by means of which a calculus as large as a hen's egg was successfully removed. Although the operation was done under local anesthesia, Josepha showed no signs of suffering. The temperature of Josepha was always 0.6° C. lower than that of her sister. The surgical separation of the two succeeded perfectly.

At the Association of German Physicians in Prague the man with the rotating head was presented. This individual, who is an acrobat by occupation, performs the feat of turning his head completely around its axis. The contortion is accompanied by considerable effort, as in addition to other complications the trachea is shut off and the resulting dyspnea permits the abnormal position to be maintained only during a few seconds. Prof. Fischl examined the man and observed an abnormal laxity of the capsules of the cervical vertebræ and of the musculature of the neck. In addition, while turning his head the man rotates the entire cervical spine and also flexes as well as rotates.

Dr. Emil Glas has succeeded in discovering the spirochetes of Schaudinn in a chancre of the gum. The patient was a woman twenty-six years of age, who presented a circumscribed infiltration of the gum between the first and second upper incisors on the left side. There was marked swelling of the submental glands and moderate fever, but the enlarged glands were only slightly painful. In view of this fact and of the peculiar dusky red color of the swelling on the gum, and the hardness of the glands involved, the diagnosis of gingival chancre was made. Extraction of a molar tooth, which was suggested by the dentist as a possible cause for the glandular enlargement, produced no effect. In microscopical preparations from the chancre a few typical spirochetes of the pallida type were discovered in the midst of masses of other spirochetes, *Bacillus fusiformis*, and cocci. Three weeks later the diagnosis was confirmed by the development of a papular rash on the hands and feet and a scaly eruption on the scalp. In view of the highly infectious nature of oral chancres, the discovery of the spirochetes in this situation is of great importance.

Dr. Bela Konrad observed a case of Jacksonian epilepsy. The patient was a boy eleven years old, who manifested frequent convulsions, focal symptoms, facial assymetry, etc., so that after protracted observation the lesion was localized as follows: It was assumed that the diseased area was in the lower part of the central gyrus, which embraces the field of the seventh and eighth cranial nerves. The neighboring centers were also involved to a less degree. Although there seemed to be no doubt in regard to the diagnosis, on operation it was found that no macroscopical changes existed. The ophthalmoscopic examination alone had been at variance with the diagnosis, all the other symptoms being strongly in its favor. Some time later the patient died and at the autopsy it was found that no macroscopical focal lesions were present. This case should serve as a warning in diagnosis, and proves that Jacksonian epilepsy, focal symptoms, and monoplegia may exist without macroscopical changes.

Eugene Remete describes a new treatment for genitourinary conditions by injecting about 10 c.c. of either physiological salt solution, weak cocaine solution, or Schleich's solution into the sacral canal. The injection is made through the hiatus sacralis, and as the spinal cord and its membranes stop at a much higher level, there is no danger of injuring them, the injection really being epidural. The injection may be repeated several times. Remete treated in this way several sexual neuropathies and anemic cases in order to determine the value of the method in regard to the direct effect exerted on the terminal nerves and vessels. Cathelin states that the injection has a shock-like effect on the centers of the conus medullaris, and produces disturbances of molecular equilibrium. According to the results obtained so far, partial success is obtained in enuresis, while in the sexual neuropathies whatever effect obtained is only temporary or due to suggestion.

OUR LETTER FROM THE PHILIPPINES.

(From Our Special Correspondent.)

THE MANILA MEDICAL SOCIETY—THE CHOLERA—THE LEPER COLONY AT CULION—PERSONAL.

MANILA, P. I., January 31, 1906.

AT the January meeting of the Manila Medical Society, no regular papers were read; the annual election of officers took place instead. Dr. Maximilian Herzog, pathologist of the government laboratory, was elected president, and Dr. Paul G. Woolley was reelected secretary.

The city of Manila has been almost entirely free from cholera during the past month. Only a few cases were reported, and those, with few exceptions, occurred in persons who came from the provinces within twenty-four hours of the time they first showed symptoms of the disease. The cholera situation in the provinces is not so encouraging. There has been a gradual increase in the number of cases reported, until now the daily average has reached in the neighborhood of seventy. More and more towns are becoming infected, and there is no longer a sufficient number of experienced physicians to superintend the measures necessary for the repression of the cholera at the various places at which it has made its appearance.

The principal reason for the continued increase in the number of cases is attributed to the fact that during December the disease appeared in some of the towns of Cavite province, in which are found probably the most densely ignorant people in the Philippine Islands. They refused to believe that the disease was cholera, and even if it was, they are said to have stated that it was probably a punishment sent them by God, and, as such, it would be undesirable to avoid it. Almost all of these people are fatalists, and in consequence take no measures which might insure them against contracting cholera. From the towns above mentioned the disease was carried by fishing-boats to Bulacan province, and it has been the constant re-infection from Cavite that has rendered it impossible to eradicate the disease from Bulacan. With a more effective sanitary policing of the Province of Cavite, there is every reason to believe that the disease could be definitely eradicated.

The experience of the health authorities, so far, has been that wherever modern sanitary principles were carried into effect the disease disappeared in every instance. In other words, it has been clearly demonstrated that if the intelligent cooperation of the people of the infected towns could be had, the disease can be stamped out in comparatively few days. As the educational work in the islands advances, so will the dangerous communicable diseases cease to be a menace in the Philippines.

The Culion Leper Colony is now almost ready for the reception of the first lepers. It only awaits the installation of a few pieces of machinery to make it complete. It is proposed to send first those lepers which are at the present time confined to the leper colony at Cebú. There are in the neighborhood of three hundred and fifty lepers at the latter institution. At the new location it will be possible to give the lepers much more liberty than they have enjoyed heretofore. The island of Culion is to be entirely set aside for their benefit, and they will be allowed to indulge in fishing, growing cocoanuts, and engage in other agricultural pursuits.

It is the intention to give them a large measure of self-government, permitting them to select their own mayor and councilmen, appoint their police, and generally carry out the public duties that are required in modern municipalities.

Major Wm. D. Crosby, medical officer in command, First Reserve Hospital at Manila, has been relieved from further duty in the Philippines, and will proceed to the United States with Major-General Corbin, who will be relieved from duty in the Philippines to-morrow, February 1, 1906, by Major-General Leonard Wood.

Dr. Paul G. Woolley, who has been director of the serum laboratory of the Bureau of Science during the past few years, has accepted a position with the government of Siam in the capacity of director of their pathological laboratory, which they propose to start as soon as Dr. Woolley can reach Bangkok.

Progress of Medical Science.

New York Medical Journal, March 3, 1906.

A Point in the Technique of Breast Amputation for Cancer.—R. F. Weir states that some ten years ago he found that in following up the enlarged lymphatic glands to the very point where the axillary vessels pass under the clavicle, he could often carry the finger under the clavicle to one of the sides of the vessels by pulling the arm vertically upward and then reach the gland, well under and slightly above the clavicle. This procedure has become a fixed rule in his breast cases. When no enlarged glands can be felt through the skin of the neck, the little or forefinger can be carried in this way under or beyond the clavicle its full depth into the neck, and the supraclavicular space behind the sternomastoid muscle fully explored. If enlarged glands are found in the region, the customary incision is made along the edge of the clavicle to the root of the sternomastoid muscle and up a short distance along its posterior border, the space cleaned out of glands and fat tissue. If nothing is found, the breast wound is closed as is usual, save that he prefers to place a small cigarette drain in the hole bored alongside the vessels, to be withdrawn at the end of twenty-four or forty-eight hours. In nearly one-half of his cases he has been able in this manner to find enlarged glands not recognizable by examination before the axilla was opened.

Gonococcic Infections and the Physician's Responsibility.—J. B. Clarke enumerates as possible gonococcic infections balanitis, cavernitis, cowperitis, periurethral infiltration or abscess, and stricture from anterior urethritis; from posterior urethritis, prostatic inflammations, spermatocystitis, and gonorrheal cystitis, which may travel up to the renal pelves. The latter group arise from a lesion marked by chronicity, resistance to treatment, proneness to recur, and an uncertainty of definite and permanent cure. These cases are the ones so often affecting the wives of patients. General infection may result in gonorrheal rheumatism. In children we may have even vaginitis, stomatitis, pelvic inflammations, and ophthalmia. The author traces the course and development of pelvic disease in young women who marry men with uncured gonorrhea. The latest form, the most common in women, presents the great danger of being ever ready to extend, when a favorable opportunity offers, to the uterus and adnexa. He says that if we compare, from a social point of view, the importance of syphilis to gonorrhea, the latter is one hundred times as dangerous as the former, not alone from the standpoint of the number of patients attacked, but also from that of the gravity of the lesions and their perpetuity. All these sad results come from ignorance. The only key to the situation is the light of true knowledge, and the only source of light at present is the medical profession. Authoritative statistical evidence presents the truth of the author's contentions in a startling light.

Suggestions on the Nature and Treatment of Rheumatism.—W. E. Deeks reviews the various theories which are extant regarding the nature of the rheumatic poison, and notes that there are many painful conditions regarded by profession and laity alike as rheumatism, but which in reality have nothing whatever to do with this affection. His own experience has led him to believe that the disease is invariably associated with some stomach disorders of the hyperacid or fermentative type. He concludes that the stomach condition is either the primary factor, or at least an antecedent feature, preparing the way for the invasion of some specific organism. He discusses the common type of dyspepsia and the function of the stomach. He notes, among other facts, that a large part of the ingested sugar undergoes fermentation in the stomach (before it reaches the bowel) by being acted on by the various organisms in that viscus, and that lactic acid is one of these products. Hence we have a fruitful source for this compound, without taking the muscles into the reckoning. The foregoing fermentative processes do not occur in every person. The rheumatic diathesis is probably associated with deficient power in the assimilation of carbohydrates. As to treatment, he notes that salicylic acid is a powerful agent in preventing fermentation of all kinds, including lactic acid. But the matter of primary importance is the regulation of the diet. For a time, at least, there should be an absolute exclusion of sugar and potatoes, limitation of bread, particularly of toast. If fermentation still exists, the administration for a few days of dilute nitric acid in twenty-drop doses, well diluted, before meals; or if constipation be present, rhubarb and soda after meals is indicated. Some one of the salicylic acid series internally, such as sodium salicylate, etc., in physiological doses should be given; and, finally, the administration of counter irritants and electricity, either static sparks or high-frequency currents. When the patient has been a sufferer for a long time, complete recovery is somewhat delayed, as there is undoubtedly some more or less chronic inflammatory tissue which is slow to resolve.

American Medicine, March 10, 1906.

Experimental Methods in Sanitary Science and Sanitary Administration.—William T. Sedgwick says, in sanitation, experience must largely take the place of experiment. He refers to his own studies on an epidemic of typhoid fever, and remarks that comparatively few physicians or sanitarians are in a position to conduct artificial experiments, but almost any wideawake observer, whether he be physician, physiologist, sanitarian, or engineer, may, if he will, find going on all about him natural experiments, the conditions of which may often be learned with great accuracy, even after the experiment is completed, and which may yield conclusions quite as capable of verification as are those of experiments made in the laboratory. This is a matter of encouragement, especially for younger workers. He pleads for better material on Boards of Health, claiming that it is time we should cease experimenting with political appointees and begin experimenting with something better than spoilsmen. Too often a hack politician or two, a second-rate doctor or two, and one or more vain or place-seeking nobodies—useless but not harmless—make up our local boards of health; and as no stream can rise higher than its source, the services of such boards are disgracefully small in quantity and poor in quality. The present plan is a failure experimentally demonstrated; let us continue to invoke the experimental method in which we believe, but abandoning our present customs, which have been experimentally proved—for the thousandth time—to be hopeless, try instead something more promising.

Review of Recent Observations on Treponema Pallidum of Syphilis.—Charles A. Pfender calls attention to the nomenclature of the organism now almost universally conceded to be the etiological factor in the production of syphilis, and states that under the International Code the present correct name of this protozoon is *Treponema pallidum*. He states that thus far, *Treponema pallidum* has been found in over 300 cases of syphilis, and not found in 62 cases examined. Most of the cases which resulted negatively were of tertiary form, while others were undergoing active treatment at the time of examination. In only one out of 138 cases of nonsyphilitic disease examined was *Treponema pallidum* reported. He further states that in view of the results of the experiments made on monkeys and anthropoid apes, the negative results in attempts to demonstrate *Treponema pallidum* in nonsyphilitic diseases, and the numerous positive observations on syphilitics, it is exceedingly difficult to escape the conclusion that *Treponema pallidum* is the organism which produces syphilis. He gives a detailed description of a number of stains, and the various methods employed by different observers in the study of the *Treponema*, and appends an extensive bibliography.

Outlook for the Chronic Dyspeptic.—Mark I. Knapp asserts that the outlook for the chronic dyspeptic is of the brightest. The disease may be due to organacidia gastrica, which he considers under three heads: Organacidia gastrica simplex, produced by the ingestion of large quantities of organic acids; gastrosia fungosa, due to mold growth in the stomach; and zymosia gastrica, due to the growth of yeast in the stomach. Insufficientia pylori, due to a gradual weakening of the pyloric sphincter, is also cited as a very frequent cause of the disease. Organacidia enterica is given as the third cause of chronic dyspepsia, and this the author discusses under the following heads: Acute organacidia enterica, acute enterosia fungosa, chronic organacidia enterica, and chronic membranous enterosia fungosa.

Appendicitis; When to Operate.—S. Edward Sanderson says the true and ample diagnosis takes into consideration the local condition, the virulence of the infection, and the balance established by the patient's reaction to these. Using the local condition as a standard, he divides the disease into the following stages: (1) The disease process is confined to the appendix; (2) the peritoneum is beginning to become invaded by bacteria and toxins penetrating the unbroken wall; (3) an active peritonitis is well under way, still localized; usually with pus formation, with or without rupture of the appendix; (4) a spreading peritonitis is attacking the general peritoneum; (5) a general peritonitis exists, with or without pus; (6) the general peritonitis is subsiding and a local walled-off abscess exists in the right iliac fossa or in the pelvis; (7) nothing remains but a local process (a) with pus, (b) without pus. Dr Sanderson believes the safest general rule is to operate only when general peritonitis is not present. Await symptoms of localization. If a surgeon's own experience and

skill allow him to be more venturesome, he may accept more cases at this stage for operation. It seems greatly to be desired that the profession should adopt a common basis upon this, if it is at all possible. In regard to late operations, no one questions the advisability of evacuating pus. In regard to internal operation, the only question which arises is whether we shall operate if a patient has safely passed through his first and only attack. If it has been unquestionably an inflammation of the appendix, especially if after-symptoms remain, operation is indicated; but if the symptoms are mild, and clear up entirely after the attack, it is generally conceded to be best to await symptoms of an oncoming second attack before operation, in the meanwhile keeping the patient under close surveillance.

Journal of the American Medical Association, March 10, 1906.

Uterine Myomata and Malignant Disease.—T. S. Cullen calls attention to the danger of incomplete examinations after hysteromyomectomy as regards the possible existence of malignant disease. He has been surprised to find how frequently myoma is associated with carcinoma in the large experience at the Johns Hopkins Hospital, and in 1903 he advised opening the uterus immediately on its removal to ascertain whether or not by any chance carcinoma of the uterine body existed, and he now recommends not only the careful examination of the uterine cavity, but also of the myomatous nodules. As an illustration of this, he reports a case of supravaginal hysterectomy supposedly for simple interstitial and subperitoneal myomata. Two years later sudden collapse occurred, due to hemorrhage from sarcoma of the cervical stump. Reexamination of the original tumor showed typical sarcomatous changes of the myoma. The patient died eight months after a second laparotomy and about two months after progress of the growth had necessitated an operation for obstruction of the bowels. The case, he says, clearly indicates that physicians should examine carefully, not only the uterine cavity, but also the myomata, before the cervical stump is closed.

Blood Platelets.—Mary W. Rowley gives figures of blood plates much larger than those from one to three microns in diameter usually described. She has found these larger forms present in cases of pernicious, splenic, and severe secondary anemia, and also in malaria, myelogenous leukemia, and in normal blood. In the last three a modification of Wright's stain was employed. While admitting that the larger size may be due in part to squashing, as it is most evident at the periphery of the blood smear, where the leucocytes also are enlarged, she thinks that another reason is that, with the ordinary technique, only the central deep-stained portion is visible at all. The periphery remains unstained and invisible, except when the platelet lies on a red cell. With the modified Wright stain used, the definite, usually rounded outline of the periphery is distinctly shown. She believes that with a suitable staining method plates similar to those figured can be found in all or nearly all blood, normal and pathological. She is now trying to work out such a method.

Carcinoma of the Prostate.—H. H. Young gives the results of the study of fifty cases of cancer of the prostate and describes the radical operation performed by him, including the excision of the entire prostate with its capsule and urethra, and the adjacent portion of the bladder, the seminal vesicles, and the ampulla of the vasa deferentia. He considers this a common disease, existing in about one-seventh of the entire number of cases of prostatic enlargement in men over fifty. Induration and pain are common, and aid the early diagnosis. The growth is often slow, confining it within the limits of the firm prostatic capsule for a long period. He claims that his operation, which is necessary for its cure, is not difficult, and gives very satisfactory functional results, and that with early diagnosis the mortality should be *nil*, and the percentage of cures large. Every indurated, enlarged prostate should be suspected, and a perineal operation advised, when, if malignancy, be discovered, the radical operation can be resorted to. The article is illustrated.

Treatment of Aneurysm by Direct Gradual Arterial Closure.—The advantages of utilizing the method of active clot formation for the cure of aneurysm are pleaded by R. T. Stratton, who points out that it is the natural method when spontaneous cure occurs, and also that by which the best results have been obtained in the surgical treatment of the condition. He reports in detail a case of aortic aneurysm thus treated by a constrictor applied above the sac and gradually tightened. The patient did well for nearly two days, but then rapidly failed with sensory and motor paralysis of the lower limbs, and died on the second day after the operation. The autopsy showed that the constriction had been applied above the celiac axis, the aneurysm extending above that branch; the death was attributed to inhibition of the functions of the abdominal viscera by the final withdrawal of the blood supply. There was no perceptible evidence of injury of the vessel at the point of constriction, and the sac was fairly well filled with a stratified clot of the active type, in spite of the short time that had elapsed. Notwithstanding the fatal outcome of this case, Stratton considers that it warrants a hopeful future for this method. The ease with which the constriction was borne by the patient; the formation of a large mass of laminated coagulum; the apparent maintenance, up to the last closure, of the lumen of the arterial branches arising within the sac and distributed to the vital organs; and especially the freedom of the aorta itself from evidence of traumatism, inflammation, or necrosis, all form the basis of a belief that this method will be available for many cases of otherwise hopeless aneurysmal disease. Its chief field of usefulness will undoubtedly be found in cases of aneurysm of the abdominal aorta, where ligation is almost necessarily fatal, and other methods are either impracticable or still more dangerous. He points out, nevertheless, still other conditions in which he thinks it will be of value and preferable to the ligature. The advantages of gradual occlusion over ligation in cases in which arterial branches supplying vital organs arise from the sac are obvious. The article is illustrated.

Fecal Impaction of the Rectum.—T. C. Martin reports cases of this condition and describes its causes and treatment. The usual recommendation is to anesthetize the patient and to employ irrigation. The object of his paper is to point out the advantages of the use of the proctoscope in these cases. The treatment consists in the elevation of the patient's hips, introduction of the proctoscope, withdrawal of the obturator, and illumination of the rectum, for which purpose he has devised a special candlestick, which he describes. Through the proctoscope, by means of forceps and spoon, the impacted masses are easily removed without manual contact. Recurrence of the condition is to be prevented by removal of any obvious cause, such as valvular obstructions, etc., and limiting diet to meat, fruit, and vegetables containing little starch. Bathing, free drinking of water, enemas, massage, and exercise are advised. Cathartics are condemned in these cases.

The Lancet, February 24, 1906.

Massage of the Stomach in Flatulent Dyspepsia.—This procedure is commended by H. Statham, who records the case of a man in whom the attacks of flatulency came on without apparent cause, often lasted several hours, and produced severe prostration. All drugs were without effect. Finally vigorous kneading movements of the stomach were made and sounds could be elicited suggesting the passage of gas from the stomach into the duodenum. Later the gas was passed per anum. The explanation of the relief afforded is that the stomach was paralyzed by its extreme distention which was relieved by the kneading movements.

Recurrent Herpes Gestationis.—An interesting case of this rare condition is reported by C. A. Bryan, whose patient was a woman of 36 years. The author believes that pregnancy is not merely a predisposing factor but is really the existing cause, some peculiar toxin elaborated during pregnancy, acting on the nervous system. This toxin is probably developed by some morbid change taking place in the ovaries as instanced by the usual aggravation of the skin lesions at the monthly epochs and also by its continuance for a short time after the termination of the pregnancy. In some cases it is justifiable to induce premature labors if the patient's health is affected by the insomnia caused by the pain and prostration. Drugs are generally without effect.

Oral Sepsis.—S. Spookes comments on the well-recognized fact that the mouth is the breeding place for many infectious organisms, and enumerates the following causes of oral sepsis: Neglect in cleaning the teeth, existence of cavities in them, alveolar abscess, difficult eruption of lower wisdom teeth, leading to ulceration of the gums; deposition of tartar from the saliva, which, in addition to favoring the retention of organisms and food products, separates the gum margin from the necks of the teeth and the various forms of pyorrhea. Treatment begins with thorough mastication. Our forefathers were not in a hurry to catch trains, and took time to chew their food thoroughly; their food was hard and toughed, and required more mastication, and this resulted in a large flow of saliva, beneficial not only for gastric digestion, but also for the teeth. All carious teeth should be made effective or removed. Tartar deposits must be taken off and antiseptic mouth rinses freely used. In pyorrhea all calcareous deposits must be thoroughly removed and the pockets disinfected with

peroxide of hydrogen. If the gums are very redundant the pocket may be abolished by rinsing the loosened gum with the electro-cautery. Some cases have been benefited by the injection of vaccines prepared from the micro-organisms found in the respective cases. These produce an increase in opsonic power, and improvement in general and local conditions follows.

British Medical Journal, February 24, 1906.

Epistaxis and Calcium Chloride.—H. S. Ware prescribes the remedy in twenty-grain doses, to be given at intervals of two hours if necessary, and then, whether the bleeding stops or not, to withhold the remedy for several hours. Its persistent administration will diminish, not increase the coagulability of the blood.

Shellfish, Seaweed, and Sewage.—Commenting on the fact that the growth of one of the seaweeds called *Ulva latissima* in any quantity depends on sewage pollution of the water in which it appears, J. T. Nash notes that he found fragments of this weed on some mussels purchased in a market. In the same mussels also he found evidences of sewage pollution, for they contained the *Bacillus coli communis* and *Bacillus enteritidis sporogenes* in large numbers.

Salicin in Acute Rheumatism.—A. J. Garland believes that salicin has a distinct influence in preventing rheumatic heart complications. When the case is first seen, he orders fifteen to twenty grains of salicin every two hours until the symptoms improve, then gradually decreases the dose, and when all symptoms have disappeared, discontinues it gradually by diminishing doses, and increasing the intervals between them; the usual result of this treatment is, that in two or three days the symptoms have nearly all disappeared, whereas most cases, in his experience, that have been treated with the salicylates, drift into endocarditis, with permanent valvular lesions. Salicin is a tonic, the salicylates depressant. If we accept the theory that acute rheumatism is of microbic origin, we can understand the excellent effects produced by flooding the tissues with salicin, from its germicidal action.

Intrahepatic Calculi.—A case of this nature is reported by H. R. Vachell and W. M. Stevens, who, at the close of their paper, review briefly the literature of the subject. Their patient was a man of fifty-two years, who gave the usual symptoms of obstructive jaundice, and finally died in coma. Peculiar features of the case were impaired health ever since the age of eleven years, when he had typhoid fever, the non-appearance of jaundice until about three weeks before death, freedom from fever until one month before the fatal result, and a normal or subnormal temperature during the latter weeks of his fatal illness (although an abscess was found on autopsy between the diaphragm and the liver, with other foci of suppuration), and a gall-bladder free from signs of cholelithiasis. The *Bacillus coli* was isolated from the abscesses on the surface of the liver, which weighed ninety-seven ounces. Several pictures of the organ are given, showing calculi *in situ*. No less than 520 separate stones were found, the largest weighing 270 grains. The hepatic ducts through the whole organ were dilated and in many places there were large cavities, with a shining internal lining. These contained calculi, mucus, and bile, but no pus. No typhoid bacilli were anywhere found.

Whitlow and its Treatment.—G. B. Mower White enumerates as the varieties of whitlow, the subcuticular, subcutaneous, thecal abscess, and subperiosteal abscess. The cause of all is generally a streptococcus. If the infection is beneath the skin the tendency for the inflammation to spread is greater than if the inflammation begins superficial to the cutis vera. In the subcuticular variety, we should avoid deep incision for fear of introducing the infection beneath the skin. We should immerse the finger in a hot solution, so as to soften the cuticle as much as possible, and with the scalpel held flat, shave off the cuticle until we have opened the inflammatory focus and evacuated the drop of pus. The next variety is the commonest of all, the subcutaneous, and the treatment is early incision through the top of the finger, through the fibrofatty pad, sufficiently deep to expose or incise the whole thickness of this pad, but not so deep as to run any risk either of incising periosteum of the bone or of opening the tendon sheath, which ends over the front aspect of the terminal phalanx of the finger. With these two reservations, a free incision, which can be done without giving an anesthetic, should be made in the middle line, directly through the fibrofatty pad of the finger. In the thecal abscess we should make the area bloodless by an Esmarch bandage under general anesthesia, incise the skin and subcutaneous tissues, and then find, if it is necessary to open the tendon sheath. If in doubt, tap the sheath with a needle, and if the fluid is turbid open the theca. The incision should traverse the site of infection, and a second incision should be made at the other end of the tendon sheath. The latter should never be laid open from end to end, for then the tendons stand out from the finger and invariably slough. The treatment of the fourth or subperiosteal variety of whitlow is comparatively simple. It consists in making an incision through the fibrofatty pad at the top of the finger down to the bone. Care should be taken not to cut so high as to endanger opening the tendon sheath. This incision gives free drainage; about a month later one is able to remove so much of the ungual phalanx as has necrosed. With few exceptions the base of the bone with the attachments of the flexor and extensor tendon survives and the wound heals without further trouble. Lead and spirit lotion (ʒss of each to 1 oz. of water) is the best application for all forms of terminal whitlow. The after-treatment of all forms consists in manipulation and massage. The paper brings out many interesting anatomical details, and is well worth reading in its entirety.

Berliner klinische Wochenschrift, February 19, 1906.

Observations on Abdominal Hysterectomy for Cancer.—Veit says that in order to gain the confidence of the laity sufficiently to induce women with uterine carcinoma to seek medical aid at as early a date as possible it is essential to reduce the mortality of the operation to such a point that it will be comparable to the risk attending laparotomy for other causes. This has heretofore not been the case, and the author ascribes the bad results in this particular operation chiefly to three factors: infection through germs present in the cancerous tissue, the dangers of the anesthesia, and complications such as pulmonary embolism through infection of the veins. In cases in which the operation is performed early the danger comes chiefly from infection through germs contained in the new growth, while in those that are more advanced cardiac failure is a more important cause of death. In order to combat infection from the growth itself Veit advocates the use of what he terms subjective disinfection by means of injection of antistreptococcus serum. The dangers attending anesthesia he reducees by performing his operations under spinal anesthesia, which he says he has found perfectly satisfactory. Complications originating in the large veins are to be avoided by more careful hemostasis and to effect this it is important to locate and ligate the afferent arterial trunks early in the operation; by doing this troublesome hemorrhage is never encountered. In the last twenty operations of this sort performed by the author only two deaths occurred, and Veit asserts his belief that these also were avoidable and ought not to have taken place.

Marmorek's Antituberculosis Serum.—Hoffa says that the contradictory statements that have been published in regard to this serum lead him to express his own conclusions in regard to it. He has used the preparation in his clinic and polyclinic for two years and about forty cases of all sorts of bone and joint tuberculosis have been treated by its means. No undesirable effects on the course of the disease that could be ascribed to the serum were over observed. Severe advanced destruction of tissue was not checked by the serum, though in some instances extensive osteomyelitic processes were brought to rapid cicatrization or cure, and in many cases the serum exerted a favorable influence on the temperature, general well-being, and the local condition. Abscesses were healed more quickly than usual. On account of the tendency to disagreeable local reaction when the serum was given subcutaneously the author was led to try its rectal administration. The result was so satisfactory that he has made this the routine method and states that the serum may in this manner be administered for months at a time without giving rise to any local or general serum reaction. While it is still too early to offer definite conclusions Hoffa counsels further investigation of this apparently useful agent.

Münchener medizinische Wochenschrift, February 20, 1906.

Suture of the Patella.—Schäfer describes a method of treatment for fracture of the patella originated by Witzel, which is free from the objections usually urged against the ordinary operative procedures employed for this injury. A short, preferably slightly curved, trocar is pushed through the quadriceps tendon above the patella, and another one through the ligamentum patellæ below. The stylet is removed from each and through each cannula a silver wire is threaded, the ends being united over a compress placed over the broken bone. In order to avoid interposition of the lacerated bits of fascia between the bone fragments, the skin and underlying soft parts are forcibly drawn upward and downward respectively by the operator and an assistant immediately before the trocars are introduced, while at the same time the bone frag-

ments are approximated. The procedure can be carried out under local anesthesia, and at the expiration of from five to eight days daily massage of the musculature can be begun. With the beginning of the third week passive, and then active, movements are commenced, and the wires are removed at the end of from four to five weeks. The treatment is finished at the end of six or seven weeks. The simplicity, safety, and effectiveness of the method are strongly emphasized by the author.

The Radical Operation for Femoral Hernia.—Berndt proposes the following modification of Lotheissen's operation for this condition. The skin incision is made parallel with Poupart's ligament and the hernial sack is isolated, tied off, and removed in the usual way. The inner extremity of the skin incision is then drawn upward and inward so as to expose the external ring, and the fascia of the external oblique is slit up in the direction of its fibers for a distance of five or six cm. The spermatic cord, or the round ligament, is then worked inward and backward until the inner side of Poupart's ligament and the horizontal ramus of the pubic bone are exposed. The sutures are then passed through the lower border of the internal oblique and transversalis, and, under the guidance of the finger passed through the external opening of the femoral canal, Cooper's ligament. The sutures are brought out of the femoral canal, the upper end of each being drawn through by means of a clamp pushed up from below. More than three or four sutures are seldom required, and after all have been passed they are tied, beginning with the one lying most externally. The cord or round ligament is then allowed to slip back into position and the incision in the external oblique is closed. The outer surface of Poupart's ligament is fixed to the fascia of the pectineus with two or three further sutures. In this way the femoral canal is completely obliterated, its inner opening being shut off by a broad muscular wall while its outer aperture is closed by the last-mentioned sutures and the canal itself is narrowed to a crevice whose walls become adherent. The author considers this procedure superior to Lotheissen's in ease of execution and serviceability.

Deutsche medizinische Wochenschrift, February 22, 1906.

Artificial Ear Drums of Paraffin.—Hamm says that the various artificial ear drums that have been suggested by different aurists are all open to more or less serious objections, the most important of which is the fact that none of the materials used for the purpose are entirely free from irritating properties. He advises the application of paraffin having a melting point at 45°C. for this purpose, and states that this substance is absolutely unirritating. On several occasions patients have worn ear drums made in this way for three or four months without experiencing any undesirable effects. If the drum has been applied prematurely so that some suppuration continues after its insertion no harm results, for the secretion readily loosens the paraffin and causes the drum to be expelled together with the discharge. The technique of application is as follows: The edge of the perforation is cocainized and dried off; the aperture is then covered with a piece of sterilized gauze which has been dipped in melted paraffin and is gently pressed into place. The paraffin hardens in a very few moments and effects an air-tight and water-tight closure of the opening so that the patient may bathe without danger. It is advisable to warm the speculum and forceps and to warn the patient to hold still, otherwise the paraffin may solidify before the drum is in position, thus necessitating another attempt.

Acute Iodism and Thyroiditis.—Lublinski refers to the well-known propensity of iodine when given internally to cause swelling of the parotid gland, an observation which he had occasion to make quite frequently in treating syphilitics in the polyclinic of the Berlin University. Swelling of the submaxillary glands is less frequent but the author has observed three instances of it. It is still more unusual for the typhoid to be affected by the administration of iodine, but several cases have been reported in the literature and the author adds one of his own to the number. The patient was a woman of 52 years, who four days after taking 20 c.c. three times daily of a 5 per cent. potassium iodide solution developed well-marked uniform swelling of the thyroid gland. On stopping the medication the swelling subsided and on resuming the use of the iodide the enlargement promptly reappeared. The author states that the observation is particularly interesting owing to the fact that the thyroid gland is the only organ which contains iodine *per se* and experiments on dogs have shown that the thyroid gland is a site of predilection for the deposition of iodine.

An Apparatus for the After-treatment of Pneumothorax.—Seidel says that although considerable time has elapsed since the introduction of the pneumatic principle in performing intrathoracic operations devised by Sauerbruch and others, the methods have not as yet been very widely tested. This is largely due to the expensive and complicated nature of the apparatus required and to the technical difficulties involved. A feature of considerable importance is the fact that owing to the extreme susceptibility to infection of the pleura, in most cases surgeons would be adverse to closing thoracic wounds without drainage, and if such openings are left the pneumothorax which such pains were taken to avoid by the pneumatic apparatus at once ensues, as it is impracticable to keep the patient for an indefinite period in the apparatus. Seidel presents a device intended to overcome this difficulty. It consists of a shallow, metal box having a glass lid which can be fastened down air-tight, while the bottom consists of a movable plate having a large central opening. Suitable inlets and outlets are provided to enable connection to be made with a water suction pump, a manometer, and a receptacle for receiving the secretions. The apparatus is placed over the wound in such a manner that the opening in its bottom corresponds to the line of incision and the soft rubber collar forming part of its lower edge is affixed to the patient's body by means of adhesive plaster so as to form an air-tight joint. The interior of the box is filled with dressing material and the movable bottom pressed against the skin by two screws; the object of this feature being to prevent the formation of cutaneous edema when suction is made. A negative pressure of any desired degree may thus easily be secured and in most cases it will be possible to leave the apparatus in position long enough to enable pleural adhesions to form and thus preclude the possibility of collapse of the lung when the suction is stopped.

The American Journal of the Medical Sciences, January, 1906.

A New Method of Operating on Dupuytren's Contraction of the Palmar Fascia.—W. W. Keen cites the history of a case in which he successfully used neural infiltration. The diffusion of nodules all over the center of the palm of the hand was such that the ordinary operation for dissecting out the contracting bands would have done no good. Before the operation, the skin just above the wrist over the median and the ulnar nerves was infiltrated with a solution of beta-eucaine and adrenalin. A few drops of this solution was injected into these two nerves which had been exposed. Scarcely any diminution of sensation, however, was produced by the infiltration. Into each nerve was then injected four or five drops of a 4 per cent. solution of cocaine. Within three minutes the operation was begun without the slightest pain. The writer removed the entire palmar fascia by lifting a flap consisting of all the tissues of the palm down to the sheath of the tendons. The incision was begun at the ball of the thumb, going down almost to the web between the forefinger and middle finger, crossing thence to a point just above the web between the ring and little fingers, and up to a point corresponding to the beginning of the incision on the other side of the hand. By lifting this flap, enough nourishment to it was retained to prevent sloughing, at the same time rendering the palmar fascia entirely accessible for removal. By simply undermining the skin, the parts going to the index and little fingers were reached with perfect ease. The results of this operation were most happy.

The Success Which Attends the Operation of Cataract Extraction.—Samuel Theobald, in speaking of the causes which have contributed to the improvement of results in cataract operations, believes that the method of operating for senile cataract which we owe to von Graefe, is perhaps the most far-reaching of these. The introduction of this method marked a new era in the surgery of cataract. Koller's discovery of the anesthetic action of cocaine ranks next in importance. Surgical cleanliness contributes materially to the success of operations upon the eye. Skilled nursing, improved hospital facilities, provision against postoperative accidents afforded by various well-known contrivances, and the more definite specialization of eye surgery, are other causes which concern the present day success in cataract operations. As to the failures which occur in this work, it must be remembered that a goodly proportion of cataractous eyes are unsound in other respects; that as cataract is especially a disease of advanced age, its subjects are frequently not in the best condition for surgical procedures; and finally that the temperament of the patient has much to do with the outcome of every operation for cataract. An intractable patient is an important factor in the unsuccessful outcome of an operation.

On the Use of Opium in Myocarditis, Weak Heart, and Dilated Heart.—John H. Musser declares that there are sound clinical reasons for the belief that opium is a tonic in cardiac debility. He pleads for the continuous use of opium or morphine in myocarditis to prevent angina pectoris, or to lessen the effect or to defer the dreaded

asystole. Opium is of advantage in cases of weak heart after exhausting disease, after prolonged mental and physical pain, and without organic lesion of valves. In cases of failing compensation, with the onset of stases, especially if the patient is fretful, opium supports the heart. This drug is valuable in the gradual engorgements from myocardial dilatation, in chronic parenchymatous nephritis, and in arteriosclerosis. The second daily dose of opium greatly soothes a hypersensitive or hypochondriacal patient. The dyspnea of myocarditis is relieved or prevented by continuous small doses of morphine for a very long time, and the tachycardia of Graves' disease is relieved by this drug.

Classification of the Cases Heretofore Called Rheumatoid Arthritis.—P. William Nathan has carefully studied some two hundred cases of which records have been kept, as well as an indefinite number in which notes were not taken. From his researches he believes that there is no such thing as a distinct disease, rheumatoid arthritis, and that polyarthritis is a many-sided subject which still presents many unsolved problems and which must still be studied from a broad and unbiased standpoint. The various cases heretofore known as rheumatoid arthritis, the writer believes, are representative of no single pathological entity, but, on the contrary, are examples of various distinct clinical and pathological conditions which often differ greatly from one another. These the writer divides roughly into two great classes: 1. Metabolic joint diseases. (a) Arteriosclerotic form. (b) Autotoxic form. 2. Infectious polyarthitis.

Annals of Surgery, December, 1905.

The Operative Treatment of Tumors of the Bladder.—The sub-title of F. S. Watson's paper is "a proposal to substitute bilateral lumbar nephrostomy and the establishment of renal fistulæ in cases of bladder tumor, for ureteral implantation in connection with bladder resection or total extirpation and that the bladder operation be done after an interval and not together with the nephrostomies." The first part of the paper is devoted to a consideration of what has been done in times past by former methods of operation. The latter part deals with the new plan the author has to suggest. He thus states the results of operation up to the present time: If the operative deaths and rapid recurrences are combined under the one heading of operative failures; such failures are seen to have occurred in 28.6 per cent. of benign tumors, exclusive of myxoma and in 46.0 per cent. of cases of carcinoma. He thinks that the very large percentage of recurrence seems to point logically to the necessity of more radical measures in benign as well as in cases of malignant tumors, if we are to hope for better results. The suggestion the author has to make in this respect is, that total extirpation of the bladder, and of the prostate if it be involved in the pathological process be done at the outset in all cases of carcinoma that have not extended beyond the limits of the above-named structures, and in which it is believed that there are no metastases, and that the same measure shall be applied in all cases of benign growths in which recurrence has taken place after a primary operation for their removal. Ureteral implantation, which contributes, as it seems, to the surgical failures, should, he believes, be abandoned, and lumbar nephrostomy, with ligation of the ureters, done instead and at some time previous to the operation for the removal of the tumor, as it seems to offer a much safer and less objectionable way of disposing of the most difficult part of the latter operation. The technic of the operation proposed by the author is given in full, but is too elaborate for reproduction here.

The Roentgen Method in Lithiasis.—In a paper illustrated by several skiagrams Carl Beck discusses the present status of the *x*-ray method of diagnosis as related to lithiasis. He speaks of its limitations, proper mode of application, stating that the criterion of a good plate is that the vertebræ, the eleventh and twelfth ribs, and the outline of the ileopsoas muscle shall be clearly defined. A plate showing merely calculus-like shadows but failing to define the above-named landmarks is misleading and should not be relied upon as a guide for operation. His experience has taught him that it is always necessary to skiagraph the renal regions whenever a vesical calculus is suspected. He has always found, since so doing, that renal calculus existed whenever there was a concretion in the bladder. Most vesical calculi are formed in the kidneys, and thus is explained the frequent post-operative recurrence of vesical calculus. The histories of two interesting cases are given in detail.

Destroying the Urogenital Diaphragm or Pelvic Floor as a Means of Relieving Prostatic Ischuria; a New Operation.—E. W. Andrews discusses this operation, his general conclusions being expressed in the following preparations. (1) The male pelvic outlet is a narrow long ligamentous triangle, often too small for the senile prostate. (2) The overgrown prostate would not obstruct the bladder were it not compressed between the jaws of the pelvic bone. (3) The triangular ligament and urogenital diaphragm hold the bladder neck and prostate immovable between these bones. (4) On cutting away these bands the constricted overgrown mass falls back into a wider space and ceases to be obstructed. (5) Incidentally great relief of rectal reflexes and spasm results. (6) The retroprostatic pouch is abolished and the *bas fond* becomes a true funnel with its outlet at the lowest point. The author describes the operation devised by him. The initial incision was first made from the symphysis, about 8 to 10 cm. long, parallel to the ramus, the spermatic cord being drawn well forward; but now the author prefers to hold up the testicles out of the scrotum with a truss or binder and then to cut the skin and fat in a curved flap corresponding with the pubic arch. The structures of the perineum are thus freely exposed, the apex of the flap made being the pendulous portion of the penis. When traction is made the opening becomes diamond-shaped, and shows the following structures from the symphysis backward: (1) A space of fat about one-half inch wide; (2) the ligaments attaching the penis to the pubis, and the prostato-pubic ligaments between which pass (3) the crura of the corpora spongiosa each side; (4) a large vein, the dorsal vein of the penis, with two smaller arteries and two nerves. The fibers of the levator ani muscle, embracing the prostate and the inner surface of the obturator internus, come forward in the lateral part of the field, and the deep fascia fills the whole space with a strong covering, which must be cut away in front before the surgeon gets inside the pelvic floor. The internal pubic artery, and particularly a large branch to the bulb, must be avoided in doing this. The vessels here encountered are pushed aside, pubic ligament of the penis divided, the deep fascia and part of the levator ani cut off. Then traction on the penis brings into view the membranous urethra and prostate. The latter becomes more visible by section of the pubo-prostatic ligaments. The pelvic diaphragm supporting the prostate is then cut along both lateral borders. Then the whole mass, including prostate and neck of bladder, falls backward and downward. Danger of hemorrhage is lessened by the use of broad ligament forceps, cutting between them and the prostate and then using hemostatic ligatures on the stumps.

The Law of Accelerating Risk in Cancer.—E. W. Andrews advances the following theorem: (1) The risk of recurrence (or rate) in malignant growths increases as the square of the time of growth or, conversely, the risk of recurrence diminishes in the ratio of the square not of the time after incidence. The author gives rules as to how to plot the "risk curve" in a given case and one or two clinical histories to illustrate its accuracy. He claims that experience shows that we can in this way exclude with fair accuracy those cases which ought not to undergo operation. A careful application of this law puts the surgeon at a middle stage of any case almost in the position of one who has seen its full course. He feels certain that the first stages of any growth furnish the data for all the later stages, whether the tumor grows slowly or rapidly. While each case has its own rate of progression, that rate once determined will accelerate uniformly according to the law of squares.

The Use of X-Rays in Carcinoma.—W. A. Pusey declares that carcinoma tissue on the surface can with practically unvarying regularity be destroyed with the *x*-rays and be replaced with healthy scar tissue. He records the histories of two cases in which carcinomatous mammæ was converted into connective tissue showing that such a result is a clinical possibility. In the use of the rays two questions have to be considered. (1) Is the danger of metastasis in epithelioma increased by their use, and (2) is there danger of stimulating and rendering more rapid the growth in inoperable cases. The author believes that a negative reply can be given to both of these questions.

Brown Atrophy of the Heart as a Result of Cholecystitis and as a Complication of Cholecystectomy.—Bayard Holmes gives the history of a case of the above nature, his patient being a woman aged thirty-two years. Numerous attacks of biliary colic led to the performance of a cholecystectomy. In a few hours she was nauseated, pulse became rapid, face cyanotic with delirium. She died with increasing cyanosis and died in the evening of the day of operation. Autopsy revealed no hemorrhage or sepsis in connection with the wound. The autopsy findings are thus summarized: Cholecystectomy, brown atrophy of the heart, atheroma of both coronary arteries and the large blood-vessels, chronic diffuse nephritis, interstitial type, slight splenic tumor, chronic interstitial oophoritis, with hydrops folliculi, hyperemia of the pancreas. The author desires to call the attention of the profession to the possibility of a change in the heart and the larger blood-vessels due to sepsis, incident to cholecystitis, or the infection of the other natural cavities of the body, the sinuses of the head and face, the pelves and calyces of the kidneys, the appendix, the tubes, and the posterior urethra.

Book Reviews.

THE INFLUENCE OF THE MENSTRUAL FUNCTION IN CERTAIN DISEASES OF THE SKIN. By L. DUNCAN BULKLEY, A.M., M.D., Physician to the New York Skin and Cancer Hospital; Consulting Physician to the New York Hospital; Consulting Dermatologist to the Randall's Island Hospitals, to the Manhattan Eye and Ear Hospital, and to the Hospital for the Ruptured and Crippled. New York: Rebman Company; London: Rebman Limited, 1906.

THE author of this interesting monograph has a peculiar faculty for unearthing half-buried observations and forgotten facts in medicine, and bringing them together and comparing them in such a way as to throw light upon many unknown or only partially recognized truths of real importance in pathology. In his work on "Syphilis Insontium" he showed in a striking and most convincing way that this disease, hitherto regarded by the majority of the profession as well as by the laity as a reproach and an evidence of sin on the part of the unfortunate victim, might be and in a large proportion of cases actually was acquired innocently, and by those guiltless of sexual misdeeds. The fact was, of course, known before, but the recorded observations were isolated and were regarded almost as curiosities in medicine; to-day, thanks to the overwhelming array of cases collected in the work mentioned, the opinion is gaining ground that syphilis is one of the infectious diseases having scarcely any more significance of sexual fault than smallpox or diphtheria, and the conviction is even growing that the malady should be taken out of the category of venereal diseases.

The present little work has no such important mission to fulfil, yet it is one that opens up a new line of research and blazes a path which may lead to important results, not only in dermatology, but also in the physiopathology of menstruation. After a brief introduction treating of the physical changes manifested by variations in weight, fluctuations in body temperature, etc., characteristic of the menstrual period, the author reviews the clinical facts taken from his own case histories and the recorded observations in literature which show the intimate relation between the menstrual function and various cutaneous manifestations. Among the diseases of the skin which have been found to occur or to undergo exacerbation during the monthly period we find mentioned: Acne, eczema, herpes, pemphigus, dermatitis herpetiformis, papular eruptions, urticaria, edema and cutaneous nodes, erythema, erysipelas, ecchymoses and purpura, pruritus, psoriasis and dermatitis seborrhœica, hyperidrosis, chloasma and melanoderma, furunculosis and abscess, syphilis, lupus, epithelioma, scleroderma and morphœa, alopecia areata, hypertrichosis, and various other minor unclassified affections.

In explanation of the relations between dermatoses and menstruation, Bulkley considers three theories, viz., cyclic changes taking place in the general system, autointoxication of genital origin, and nervous reflex irritation from the congested condition of the uterus and ovaries, and states his belief that the effects may be produced in different cases in each of these three ways. It must be confessed, however, that there are many obscure points that need elucidation before the pathogenesis of menstrual dermatoses can be satisfactorily explained.

In the treatment of the disorders under discussion, the author advises against an exclusive therapy of the generative organs, though recognizing the desirability of treating obvious lesions of these parts. Local treatment of the skin lesions must also, he believes, play a relatively unimportant part in the management of many of these cases, for, he says, "the menstrual influence on the eruption is only the result of some derangement farther back in the life processes of the body which must be reached if any treatment is to be effectual." A really satisfactory and scientific treatment of these disorders of the skin must evidently wait upon the discovery of the mode of their production. The therapeutic suggestions contained in the last chapter of this brochure are therefore useful, but must be regarded as empirical rather than specific. The great value of the work lies less in its practical application than in the stimulus which it offers to further research. It has indicated a new field for investigation by both the gynecologist and the dermatologist, which, if industriously tilled, will undoubtedly prove remunerative.

FOOD AND DIET IN HEALTH AND DISEASE. By ROBERT F. WILLIAMS, Professor of Principles and Practice of Medicine in the Medical College of Virginia, Richmond. Philadelphia and New York: Lea Brothers & Co., 1906.

IT is a hopeful sign that medical writers are devoting themselves in increasing numbers to the preparation of works on diet, hydrotherapy, hygiene, and other non-medicinal methods of the prophylaxis and cure of disease. There are other excellent works on diet already before the profession, but that makes the present book none the less welcome. Without disparagement, we may say that the treatise before us is less scientific in its presentation of the subject of foods than some of its predecessors, for through that very fact it is adapted to the needs of a wider circle of readers. The plain, everyday, family physician has no time to study the chemistry of foods, and is little concerned with knowing the exact number of calories which a given weight of beans or roast beef will supply, but he does want to know in a general way what diet is best for his patient and how the foods constituting that diet shall be selected and prepared. This need of the general practitioner is what Dr. Williams has endeavored to meet, and has successfully met, in the book before us.

The work is divided into two parts: I., Food in Health, and II., Food in Disease. To borrow from the publishers' prospectus (which a careful examination of the work convinces us is not exaggerated): "In Part I. the needs of the body for different kinds of food, and the manner in which they are utilized, are explained. The principles of cooking and detailed descriptions of the different articles of food in common use are given, with chapters on the proper nourishment of infants, children, adults, and the aged. Part II. deals with the variations from the normal diet which are necessitated by the more common diseases, and includes a section on the general methods to be observed in feeding the sick as well as special directions for nourishment in the different diseases."

The author has the command of an agreeable style, and his book is not "dry reading" in any part. An opening chapter is given to the chemistry of food, a second to the physiology of digestion, and a third to cooking; the remaining chapters of Part I. deal with the different sorts of food and their value in nutrition. The second section treats of the special dietary indications in various diseases. Incidentally the book contains numerous suggestions and hints which are of practical value. To quote only one: In treating of coffee, the author says that "a small cup of black coffee, taken early in the morning before breakfast, will often relieve constipation," which is a fact, yet one not generally known. We can confidently recommend this work as a useful contribution to the important subject of dietetics.

A SYSTEM OF MEDICINE by Many Writers. Edited by THOMAS CLIFFORD ALLBUTT, M.A., M.D., LL.D., F.R.C.P., F.R.S., F.L.S., F.S.A., Regius Professor of Physic in the University of Cambridge; Fellow of Gonville and Caius College; and HUMPHRY DAVY ROLLESTON, M.A., M.D., F.R.C.P., Physician to St. George's Hospital and to the Victorian Hospital for Children; Sometime Fellow of St. John's College, Cambridge. New Edition, Revised Throughout with Additions. New York: The Macmillan Company; London: Macmillan & Co., Ltd., 1905.

IN the nine years since the appearance of the first edition of this first volume of Allbutt's System of Medicine, no very striking changes have occurred in the subjects of which the several articles grouped under Prolegomena treat. These subjects include, among others, medical statistics, nursing, dietetics, physical exercise, massage, life insurance, climatotherapy, hydrotherapy, electrotherapy, hygiene of youth, old age, inflammation, and fever. One entirely new subject, that of x-rays in medicine, is introduced, and another, practically new, is transferred to this volume from Volume VI. (the Editor mistakenly says Volume V.) of the old edition. The second part contains articles on some of the infectious diseases, namely, septicemia and pyemia, erysipelas, infective endocarditis, cerebrospinal fever, influenza, diphtheria, tetanus, enteric fever, and relapsing fever. These articles appear to have been very extensively revised and are, so far as a careful examination shows, thoroughly up to date. Those who know and value this excellent system of medicine will be glad to learn of this new edition, but it is disappointing to be told by the editor that it is to come out at the rate of but one volume a year. The second volume, which is promised for the end of the present year, will be largely devoted to the consideration of tropical diseases.

BERLINER ARZNEIVERORDNUNGEN. Mit Einschluss der physikalisch-diätetischen Therapie. Für Studierende und Aerzte. Nach der 4. Ausgabe des Arzneibuches für das Deutsche Reich zusammen gestellt von Dr. med. PAUL RECKZEH. Mit einem Vorwort von Prof. Dr. FR. KRAUS. Berlin: Verlag von S. Karger, 1906.

COLLECTIONS of prescriptions usually find a large and enthusiastic circle of readers, and as the present one is made in Germany we presume it will be doubly popular. It purports to reproduce the combinations of drugs most in use in the more important clinics of the Fatherland, principally those of Berlin, and seems to be well stored with therapeutic suggestions. The arrangement is not unduly impractical, and we commend the volume to those desirous of imparting a Teutonic flavor to their medication.

Society Reports.

THE PRACTITIONERS' SOCIETY OF NEW YORK.

Two Hundred and First Regular Meeting, Held February 9, 1906.

Dr. Joseph D. Bryant, President *pro tem.*

A Case of Dilatation of the Esophagus.—Dr. E. G. Janeway presented a patient, a man 51 years old, who was referred to him in January, 1904, by Dr. Jefferson Scales, of Staten Island. The only point of hereditary interest was the death of his father, from gout, at the age of 35. The patient had always abstained from tobacco and alcohol, and had no venereal disease. There was no history of any accident. He had a severe attack of pleurisy when he was seven years old, and typhoid fever fourteen years later. In June, 1896, he had an attack of so-called bronchopneumonia, with slight pleurisy, which lasted three weeks.

Twenty-two years ago he began to have some difficulty in swallowing the early part of a meal. If he started the meal with a glass of water, then the rest could be easily taken. In the early morning he would regurgitate through the nose a little of his dinner of the previous night, and, at times, in blowing his nose, some food would come away with the mucus. He also had slight cough or choking. The difficulty in swallowing seemed to him to be just below the root of the neck. This went on for about twelve years, and then gradually ceased. He was supposed to have had a spasmodic stricture of the esophagus, which he had learned to control.

In May, 1900, just after getting into bed, his wife pushed him, and he spat and coughed up a mouthful of blood. This was followed by some cough, although he stated that he had coughed somewhat since his attack of pneumonia in 1896. In May, 1901, he had a slight cold, and while on his way home from business he again had a hemoptysis, bringing up about a wineglassful of blood, mixed with food. This was repeated the following June. He then went to the mountains, and there, after a walk up-hill, he again raised blood. Almost every night he coughed and raised mucus containing particles of food. His next hemorrhage occurred in November, 1901, and from that time until the following May it recurred about once every month or six weeks. The following August, while again in the mountains, he spat up small quantities of blood on several occasions for a period of three days. At that time the lungs and sputum were examined, and both were found negative. A physician who saw him then thought the bleeding came from the pharynx, and kept him in bed for a week, giving ergot and local treatment.

His next hemorrhage occurred in December, 1902, and a repetition in February, 1903. Then he went to Pinehurst, N. C., for three weeks, where he had another hemoptysis. An examination of the chest and sputum was again negative. In October, and again in November, 1903, the bleeding recurred. The following December, after mounting a flight of stairs, he raised fully a wineglassful of blood, which contained considerable food. When these hemorrhages occurred, he felt a lump rising in the chest as when one belches gas, followed by tickling and cough, and then the blood appeared. Then he vomited some food mixed with blood, the former not thoroughly digested. The blood was always bright, until he had taken adrenalin. One day he bled from the nose, discharging a clot followed by quite free bleeding. This was followed by slight spitting of blood on several occasions.

In addition to the regurgitation and the bleeding, the patient had had four or five attacks of intense pain of a burning character, spreading across the upper chest. These attacks had all come on about three or four o'clock in the morning, at times when he had vomited the previous evening, and had, as he called it, "an empty stomach." This was always relieved by hot malted milk or hot water. None of these attacks had followed exertion. The last one occurred a year ago. In spite of his symptoms, the patient had gained twelve pounds in weight. He had been examined by two competent physicians, one of whom, in August, 1902, thought he detected trouble at the base of the left lung, and the other, eight months previously, at the apex of the same lung. In August, 1902, his throat had been examined, with negative results.

When Dr. Janeway first saw the patient, on January 4, 1904, he could prove nothing wrong with the lungs. The patient informed him that if he should eat a hurried meal at night he would regurgitate considerable food between two and four o'clock the following morning. The blood which he raised was always mixed with some food after the first mouthful. He was well nourished. An examination of the abdomen was negative. The blood pressure was somewhat increased. Two days later he came with a test breakfast (Ewald). On attempting to pass the stomach tube, large amounts of acid malted milk taken the night before were brought up alongside the tube as soon as the latter entered the pharynx. After several such attempts, the tube passed its full length, and more fluid contents were obtained. Neither the thick milk nor the thin contents showed free hydrochloric acid or albumose. Such sputum as he brought was tenacious mucopus, and was free from tubercle bacilli.

On January 11, another attempt to get a test breakfast resulted the same as the previous one. A large quantity of fermented material was brought up from the esophagus. A second sputum examination was negative as regarded bacilli of tubercle, though there was some blood in it. On January 14 he was again examined, having taken no food for twenty-six hours, until he took a breakfast of grapefruit with sherry, mush with milk, bread and butter, and beefsteak. On passing the tube, about 300 c.c. of fermenting, mushy material was brought up alongside the tube, smelling strongly of acetic acid. By passing the tube several times, and pouring down water each time, the esophagus was fairly well cleansed. The tube, at a distance of 44 cm. (17½ inches) from the teeth, met with an apparent obstruction, and was rather firmly held on an attempt to withdraw it. The removed contents showed no free hydrochloric acid; no proteid digestion; no starch left in solution. Ether extract left much fatty residue, and gave a strong lactic acid reaction. The odor showed acetic and butyric acids. The patient was then placed on rectal feeding for five days to allow the esophagus to rest. For a few days he was allowed barley water and albumen water by mouth. After this he had absolutely no cough nor regurgitation for the first time in years. Notwithstanding the rectal alimentation, he had lost ten pounds in weight. Passing of the stomach tube brought up from the esophagus about 200 c.c. of opalescent, mucilaginous fluid, not quite sweet smelling, but not containing acid of any kind. On this occasion, repeated attempts to pass the tube into the stomach failed, owing to its turning on itself at a distance of 17 inches from the teeth. After taking about twelve ounces of water, there was an eructation of gas, and the water could be heard to enter the stomach. After this he was allowed some food by the mouth. Rectal feeding was continued, and he regained some of his lost weight. He was instructed to wash out his esophagus and on one occasion this procedure produced a slight hemorrhage, followed by some clots and bloody mucus. On February 10 he took one pint of oatmeal gruel, and subsequently the tube brought up 300 c.c. of the gruel, barely acid to litmus. A No. 18 tube was then substituted for the No. 20; it was grasped for a time, but, after waiting, the spasm apparently passed off and the tube entered the stomach, bringing up about 50 c.c. of contents. The distance from the teeth to the eye of the tube was 23 inches. The total acidity of the stomach contents was 46; free hydrochloric acid, .0736=20. Proteid digestion good. After this the patient was put on liquid food and his esophagus was washed out daily, as it had been proven

that the case was one of dilated esophagus, with spasm of the cardia. A subsequent test of the capacity of the esophagus showed it to be twenty ounces. When the esophagus was filled with fluid, percussion showed an area of dullness to the right of the spine, which disappeared when the fluid was withdrawn and air was substituted. An attempt was made to obtain succussion sounds in the esophagus by having the patient drink some water, and then blow in air, and shake himself, but the result was negative. Since May, 1904, the patient had returned to a general diet, eating anything he felt inclined excepting tough meat. This had produced a recurrence of the hemorrhages, and he had now gone back to a more prudent diet and the proper care of the esophagus.

In connection with this case, Dr. Janeway showed an excellent radiograph of the esophagus, which was taken by Mr. Caldwell while the esophagus was filled with a pint of thick bismuth subcarbonate in suspension. This gave a beautiful representation of the dilated esophagus, with its shadow reaching that of the diaphragm.

Dr. F. P. Kinnicutt said the condition described by Dr. Janeway was generally supposed to be due to a spasmodic constriction of the cardiac orifice of the stomach, with resulting dilatation of the esophagus above the point of constriction. There was also, usually, elongation of the esophagus, and in one case that came under his observation, in which the condition had been recognized as one of cardiospasm twenty years before the case came to autopsy, the esophagus was elongated by about one-half its normal length. Its length was 18¾ inches, the normal length being about 9 inches.

Two Cases of Carcinoma of the Tongue.—Dr. Robert Abbe showed two cases of extensive carcinoma of the tongue which he had just begun to treat with radium. He showed the patients at this early stage so that the members might follow the course and effect of the radium treatment.

In reply to a question, Dr. Abbe said that so far as he knew, there was no case on record in which a recurrence had taken place elsewhere in the body after the radium treatment. Microscopical examination has been made in each of the tongue cases, and, clinically, the diagnosis was beyond question. One of the cases had been referred to him by Dr. William T. Bull, who regarded it as carcinoma, and an unpromising case for operation. Both had begun to show striking improvement, and would be exhibited again.

A Case of Round-Celled Sarcoma of the Eyelid.—Dr. Abbe presented this patient, who had already been shown at one of the previous meetings of the Society. The case was one of round-celled sarcoma of the right lower eyelid, extensively involving the inner and outer sides of the lid and its mucocutaneous border. Under the influence of radium, the tumor had entirely disappeared, leaving an apparently normal condition of the tissues of the lid. Ten months had elapsed since the disappearance of the growth, and there were no signs of a recurrence. The case was especially shown to direct attention to the fact that whereas all semblance of two-thirds of the lid had been lost in the year's growth of tumor, there was left a sharp and normal edge to the eyelid after the retrograde disappearance of the tumor.

Dr. Janeway mentioned a case of sarcoma of the jaw in a woman 84 years old. The patient had been referred to Dr. Abbe, and the lesion had entirely disappeared under the use of radium.

Dr. Abbe said that in the case referred to by Dr. Janeway, one year had elapsed since the treatment was discontinued, and he had recently heard from the patient's son that there were no signs of a recurrence. In that case, the sarcomatous growth had produced a spontaneous fracture of the lower jaw. The bone had reunited.

The Boundary Line Between Medicine and Surgery.—Dr. Edward G. Janeway read this paper (See page 409).

Dr. Henry F. Walker said that nowadays, when even serious operations were performed with comparatively little danger, it was the physician who ofttimes had to be conservative. Many patients had an idea that they could obtain immediate and complete relief by surgery, and frequently needed to be restrained, rather than urged in that respect. This change of public opinion in regard to surgery had taken place in comparatively recent years. Personally, Dr. Walker said, he was always willing to have the surgeon take charge of a case in which there was a possibility of surgery giving immediate relief, and he has always inclined to advocate prompt surgical interference rather than await doubtful improvement by medicine.

Dr. William M. Polk said that in contradistinction to the class of women who objected to having children, and who sought the gynecologist in order to get rid of what they called the onus of child-bearing, there was another type that was more difficult to deal with, namely, the sterile class who really desired children, in whom every possible minor or extraneous factor for the sterility had been corrected or eliminated, and where a grave surgical operation was the only remaining recourse to remedy the condition. Such an operation, directed to the very root of the difficulty, was not as a rule eagerly accepted by the patient, as it involved a laparotomy and a direct examination of the pelvic organs. While the operation was a serious one, the danger of it was comparatively small, and Dr. Polk said that as the result of his investigation and experience he felt justified in doing it if the patient chose to accept the risk.

Dr. L. Bolton Bangs said that while at times no doubt in common with other surgeons he had been placed in a false position by the poor judgment or the lack of judgment on the part of the medical consultant, he always felt willing to defer to the opinion of the wise, careful, thorough diagnostician that an operation should not be done, no matter what the ultimate outcome of the case might be. He recalled a case of renal calculus in which he had strongly advised operation. Before submitting to it, the patient said he desired a medical opinion, and accordingly was sent to Dr. Janeway, who examined him, and the following morning he passed three renal calculi spontaneously, which rendered an operation unnecessary. The speaker said he could cite other cases, however, in which valuable time was lost by what he considered a lack of judgment on the part of the medical men.

Dr. Lewis A. Conner said he was interested in the statement made by Dr. Janeway in regard to the doubtful advisability of making a gastric fistula in dealing with a cancerous stricture of the esophagus. The speaker said he had always been inclined to advise such a procedure, although he had never been able to follow his cases long enough to know the ultimate result, or how satisfactory or unsatisfactory such a fistula was.

Dr. Kinnicutt, in reply to Dr. Conner, said he presumed that Dr. Janeway's remarks did not refer to benign strictures of the esophagus. He recalled one such case where a gastric fistula was established, and for fifteen years afterwards the patient lived an active, useful life, and was comparatively comfortable. In cases where an artificial anus was established for the relief of intestinal obstruction of a malignant character, the speaker said he had seen life prolonged for a year or eighteen months, but such patients frequently complained bitterly that they had not been allowed to die without operation. There was one class of cases in which it was often extremely difficult for the medical adviser to reach a decision, namely, cases of obstructive jaundice, where the question arose whether an operation should be done early, or whether the patient should be given the possible chance that the obstruction would be relieved without operation. The speaker said his personal experience with this class of cases had been similar to that of Dr. Janeway, which was, that if an operation was necessary, it had better be done early than

late. In late operations, with deep jaundice, fatal secondary hemorrhage was to be feared.

Dr. Charles L. Dana said there were certain men and women, the so-called neurotic persons, upon whom the effect of even a comparatively trivial operation was often a very serious matter. There were a large number of persons, particularly young people, who were always ripe for the development of a psychosis, and an operation sometimes appeared to be the determining factor. The speaker said he could recall many cases in which an operation had produced an obsession, or neurasthenia, or hypochondriasis, and this had led him to the view that before an operation on a person of this temperament was advised or undertaken, the family and personal history should be very carefully gone into. To illustrate his remarks, Dr. Dana cited the case of a young woman who suffered from prolonged, severe neuralgic pains on the left side of the body. A prolapsed kidney was discovered, and, after a great deal of consultation and treatment, the kidney was anchored and the neuralgia disappeared. Subsequently, the patient developed intense neuralgic pains along the course of the trigeminal nerve, which were also relieved by an operation. Several months later, she developed severe ovarian neuralgia, for the relief of which the ovary was finally removed. After that, the neuralgic pains returned over the site of the original kidney, and so it went on, the patient having become, more or less, the victim of an obsession of the neuralgic habit. Dr. Dana said that many people who had neuralgias or stomach disorders, and who were of this neurotic temperament, were often made worse by either medical or surgical treatment. In regard to operations on the central nervous system for organic trouble, Dr. Dana said he believed they should be done oftener than at present. Upon such cases, especially in the line of cranial surgery, he did not think the surgeons operated often enough or well enough. In spinal surgery, the results were much more satisfactory.

Dr. Abbe said that Dr. Janeway's paper was along conservative lines, and personally he thought the most conservative person was the surgeon himself, partly from timidity, largely for the good of his patient. At times, when a new hope was roused in regard to a certain operation, it was doubtless rashly undertaken. As an example of this, the speaker mentioned the fixation of a movable kidney, which operation in the majority of cases he thought should be relegated to the past. It had been demonstrated that mobility of the kidney was very commonly met with in women who were in perfect health. In regard to the proper time for operating in gallstone obstruction, Dr. Abbe said there are legitimate grounds for delay in most cases, and cited a case where the patient was kept in the medical wards of the hospital many days until her temperature reached 105° F., and the outlook appeared to be pretty hopeless. Then the conservative physician became alarmed and transferred her to the surgeon. It was decided to operate on the following morning. That night the patient passed 134 gallstones and recovered without operation. Nevertheless, where septic or gangrenous cholecystitis is suspected, immediate operation will save most cases.

Dr. Virgil P. Gibney said that in orthopedic surgery the choice lay between conservative, or mechanical treatment, and operation, and one particular class of cases he had in mind was that of extensive tuberculous disease of the knee-joint in children. The advice often given by the attending physician in these cases was not to permit an operation, and, acting upon that advice, many cases were allowed to drift along to a hopeless stage, with prolonged suppuration, accompanied by a low specific gravity of the urine, hyaline casts, beginning enlargement of the liver; and finally these patients became waterlogged, and their end was a pitiable one. The speaker said he had seen many of these patients die in just that way, while on the other hand he had seen rapid recovery follow prompt amputation of the affected limb. It was often impossible to obtain permission to sacrifice the limb in these cases, even when the children begged for the operation, the parents refusing on the ground that they would rather see their child buried than operated on. The same was true of advanced disease of the hip-joint. The tendency now in dealing with these cases was to localize the foci of the disease, which could be quite readily done by means of the *x*-ray, and then, by operating early, the joint could frequently be saved. Even if all the foci were not removed, such an early, conservative operation might prevent the extension of the disease by contiguity, and offered a good prospect of not only curing these patients, but of leaving them without any deformity, and restoring the function of the joint.

Dr. Charles Stedman Bull said he could emphasize from an ophthalmological standpoint the remarks made by Dr. Dana, as many neurotics were inclined to locate their imaginary ills in the eye. This fact had led to the indiscriminate cutting of the ocular muscles for the relief of many functional nervous disturbances and even of more serious neuroses, such as chorea and epilepsy. This practice, which often verged upon the criminal, had, fortunately, become less frequent than formerly.

Dr. Beverley Robinson said he was not strongly in favor of an early operation in cases of so-called obstructive jaundice, in spite of the reason that had been advanced that the patient might die of hemorrhage if the operation was too long delayed. In a case that had been operated on at St. Luke's Hospital within the past year, the patient died, and at the autopsy the case proved to be neither one of carcinoma, as had been suspected, nor of obstructive jaundice. It was found to be a case of cirrhosis of the liver with a certain degree of chronic contraction of the common bile duct, so in that instance the jaundice was the result of a condition that could not have been relieved by surgery. In another case, seen more recently, the patient was a very old gentleman, whose symptoms were believed by the consulting physician to b due to obstructive jaundice, or possibly to malignant involvement of the duct. The patient died without operation, and at the post-mortem gallstones were found, but so situated in the ducts that they could not have been removed. Moreover, even if there had been a successful operation for gallstones, other anatomical conditions present would have caused a fatal ending. Dr. Robinson said that one point that had not been touched upon was whether the detection of pus anywhere in the body was always a signal for its removal. From a surgical standpoint, pus ought to be let out; from a medical standpoint, a certain amount of pus could be taken care of by the system without great risk to the patient. Another point was whether it was safe to employ massage to dissipate small collections of pus; some claimed that such treatment was attended by great risk; others claimed it was not. Another point was, whether it was better to apply heat or cold in local inflammatory conditions. With patients in whom the gouty dyscrasia was clearly defined, hot applications, in his experience, were preferable.

Dr. Joseph D. Bryant said that in the discussion of Dr. Janeway's paper, the consensus of opinion seemed to indicate that the physician and the surgeon should work hand in hand. He knew of no more embarrassing situation for the surgeon than to be hastily summoned out of town or elsewhere, and told to come prepared to operate, and to find, on his arrival, that an operation did not seem imperative, and could only be done, perhaps, at the risk of damaging the prospects of the patient. In postponing the operation in such a case, the surgeon would not only run the risk of displeasing the attending physician and possibly prejudicing the friends against him, but he would also have to shoulder the entire blame if operation were deferred and anything went wrong. While the physician is, and should be, the better diagnostician in the majority of instances, he most respectfully objected to the surgeon being

the executive agent of the physician and being expected to operate because the physician desired it, as the surgeon is better able to estimate the results of operative interference for obvious reasons than is the physician.

Dr. Janeway, in closing, said that in the case of benign stricture of the esophagus, referred to by Dr. Kinnicutt, he had raised no objection to the formation of a gastric fistula, by which means the patient had lived for fifteen years in comparative comfort. Prior to his death he had developed symptoms of bowel obstruction, with regurgitation of food through the gastric fistula, and finally convulsions, from which he died. The autopsy showed an ulcer of the esophagus, about an inch above the cardiac orifice, which had healed, leaving a very tight stricture. The bowel obstruction was traced to a polypoid growth in the jejunum, with resulting intussusception.

Plastic Operation on the Nose.—Dr. Robert Abbe showed two casts, taken before and after, of a case where he had operated to improve the contour of the nose. The patient was a gentleman who, as the result of a carriage injury, had had the bridge of his nose jammed in, producing an unsightly, flat, saddle-back nose. The operation consisted of taking a piece of pink vulcanite, such as dentists used in making plates, and filing out a thin plate of it to exactly fit the defect on the plaster cast and create a shapely nose. After sterilizing in carbolic acid, alcohol, and salt solution, this was then inserted underneath the skin through a lateral incision. The operation was done seven years ago, and the vulcanite has remained unchanged and the scar practically invisible. The contour of the nose was still so perfectly like a normal structure that it could be considered a triumph of plastic work.

The Penetrating Power of Radium.—Dr. Abbe, in order to illustrate the penetrative power of radium, showed a photographic plate upon which a revolver had been photographed by a single grain of radium. The rays had penetrated the steel, so that the cartridge with which the revolver was loaded and the internal mechanism of the lock were clearly seen in the photograph.

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Stated Meeting, Held February 26, 1906.

Dr. Floyd M. Crandall in the Chair.

Committee on Centennial Celebration.—The following subcommittees were announced: Dr. E. D. Fisher, *Chairman;* Dr. C. H. Richardson, *Treasurer. Committee on Arrangements:* Drs. Walter L. Carr, Henry S. Stearns, and J. S. Thatcher. *Committee on Speakers:* Drs. Joseph D. Bryant, A. Jacobi, and Parker Syms. *Committee on Printing:* Drs. John Van Doren Young, Charles N. Dowd, and Wendell C. Phillips. Other members of the committee were Drs. Jos. Brettauer, N. E. Brill, Charles L. Dana, Arpad G. Gerster, Alexander Lambert, Wm. M. Polk, and Richard Van Santvoord. This celebration is to be held April 4, 1906, at the Hotel Astor.

The Question of Economy in the Medical Supplies of Hospitals.—Dr. John Winters Brannan, president of Bellevue and Allied Hospitals, said that all admitted that there had been waste which seemed an almost unavoidable result of our system of hospital administration. It did not seem to him necessary to make such radical changes as suggested by Dr. Gerster in his address before the New York Academy of Medicine, November 2, 1905 (see Medical Record, December 2, 1905, page 885), having it conform to that of Germany, where the executive control and management of the hospitals were in the hands of paid medical men, who also directed the treatment of patients. Now that attention had been called to the waste in the hospitals, and its causes had been studied and analyzed, steps had been taken that promised soon to put our institutions upon a business basis. He said no method could be effective without the cordial cooperation on the part of the superintendent of the hospital, the superintendent of the training school, the visiting physicians and surgeons. In the hospitals with which he was connected the surgeons were most ready to adopt and enforce all reasonable measures to lessen waste. He presented a set of rules which specified how the surgical dressings and appliances might be used and how they must not be used by the house staff and nurses. These were posted in the operating rooms and surgical wards, and no doubt had contributed largely to the saving. At Bellevue a large reduction in the use of surgical supplies took place when the distribution to the wards was placed in the hands of the superintendent of nurses. Since endeavoring to eliminate this waste he said that in the latter half of 1905, as compared with the same period of 1904, there was a saving of 124,000 yards of dressing gauze, or 56 per cent. In bandage gauze, absorbent cotton, rubber adhesive plaster, or other surgical utensils, the results were approximately the same, and represented a saving of about $10,000 a year. The operating service was at least as heavy last year as in the year previous, and the surgeons attested that they had all the supplies they needed. On the medical side the opportunity for waste was not so great, but considerable saving had been effected by requiring that alcohol and whiskey, new and expensive drugs, should be ordered only by members of the visiting staff, and in small quantities at a time.

The Convalescent Branch Hospital and Its Relation to Hospital Reform.—Dr. S. S. Goldwater, superintendent Mt. Sinai Hospital, said that at a recent annual convention of the Association of Hospital Superintendents he urged the importance of splitting into two parts all construction funds for general hospitals, one part to be devoted to the building of a main hospital for acute cases, and the other to be applied to the erection of a distinctive branch hospital for cases no longer acute. This plan was advocated as a means of obtaining the greatest possible return for each unit of capital and labor expended for hospital purposes. He referred to the popular error of exploiting certain relatively small economies in one or another branch of expenditure, savings which, even if consummated, would leave untouched the general situation of the hospitals and the whole machinery of the community for dealing with its sick poor. He asked, for example, why in a growing community like ours was not more attention given to the *timely* reservation of hospital sites, a reform which in a decade would result in a saving of perhaps a million dollars. Why did they not decide upon the type of building which, under the conditions existing in a great city, could be most economically administered; or upon the proper size, for administrative purposes, of a hospital of any accepted type; or upon the most advantageous method or system of grouping patients in separate establishments? The study of these questions would tend to develop and to crystallize hospital policy. Unfortunately they had not been studied with sufficient care, and grievous economic blunders continued to be committed in hospital affairs. The proposition to cut off the convalescent group from every general hospital, and to house and treat them separately, was advocated mainly upon economic grounds. If the division or subdivision of patients into acute and convalescent groups were entirely consistent with therapeutic ends, the sooner the subdivision was effected, the better. He considered in turn, first, the meaning of the proposed plan from the standpoint of hospital construction; second, its effect on maintenance charges; third, its value to the patient; and, fourth, its social significance.

The Relation of the Visiting and House Staff to the Care of Hospital Patients.—Dr. W. Gilman Thompson called attention to Dr. Gerster's suggestions and urged that hospitals should employ paid medical officers, thereby commanding more of their time, and promoting economy of administration. This proposition led to the question whether continuous service on the part of the visiting staff did or did not especially benefit the patient. Classified

upon a service basis he said there were three distinct groups of public hospitals: (1) those to which any reputable physician could send patients, and personally treat them there for any period of time; (2) hospitals in which a comparatively small paid permanent visiting staff enjoyed an absolute monopoly; (3) hospitals managed upon intermediate system, with a large visiting staff and reasonable rotation of service, which was at present the prevailing type. It had never been clearly demonstrated that the results of treatment in any one of these groups were any better than in the others. It was the men employed, rather than the system which made for success or failure. It might be possible to allot a permanent service to one who soon reached his limitations of development and kept both house staff and nurses within the confines of his own narrow-mindedness. Arbitrary age limits might also aid to remedy this condition. The general standard of medical education and training had been elevated and the field of knowledge had become so broad that it was difficult to find a physician preeminent in the treatment of a certain condition. The question of continuous hospital service was somewhat different when viewed from the surgical standpoint than it was when viewed from the medical. The surgeon had his individual methods of antisepsis and operation. The frequent change of such a service would be to transfer to one's successor a number of cases, the real nature of which he could necessarily know but little. In a medical service an occasional change might prove an advantage. Again, a hospital was a great educational factor, educating its nurses, its internes, its special students, and its visiting staff to serve the community at large. In-so-far as it could increase the number of this class, its influence for good would extend. If under the charge of one man it deliberately restricted its sphere of usefulness without adequate gain to the patient. The question of economics belonged to the paid superintendent and should be met by securing greater efficiency, if need be, in that department. Proper cooperation of the visiting staff in maintaining economy was most essential. The physician's time belonged to his science and should not be frittered away with purely administrative details. Two factors that tend to interfere with the close study and watchful care which the members of the house staff owed to the patients were the so-called clinical laboratory and the over-trained nurse. While recognizing the importance of the laboratory as an aid to diagnosis, he thought that in just as far as the laboratory led the house staff away from bedside methods of close observation it worked an injustice to the patient. It was sometimes a mistake to delay treatment until positive findings were reported from the laboratory. Some hospitals had devised a system by which entering young men served in part as assistants in the strictly pathological work of the hospital and in part relieved the house staff of clinical laboratory work. This system had certain advantages. Many of the clinical laboratory tests should be made by the trained expert rather than the young interne. Too much routine laboratory work gave the interne too little time for study or to perfect himself in physical diagnosis. Nurses were required to learn about as much physiology, anatomy, and bacteriology as a first year medical student and to spend at least one-third more time in hospital service, thus getting a power and importance never intended by the medical profession. In one hospital it was found that the internes almost never applied dry cups, passed rectal or stomach tubes, or gave hypodermics. It was right that the nurses should know how to perform these services, but not that the internes should be excluded from learning these things. Some of the inflexible rules in regard to order in the wards regardless of comfort to the patient were deplored. For instance, the engineer was ordered to keep the temperature at 70°, and the pneumonia patient, burning with fever and in need of fresh air, must suffer together with the uremic in the next bed who had a subnormal temperature and needed a sweat in a hot pack. Neatness, order, and discipline must prevail, but inflexible and unthinking routine should not be allowed to deprive the suffering of reasonable individual comfort. It was in these matters that the relations of the house staff and the nurses to the patients was lamentably deficient and there was danger lest the emphasis given to the science of diagnosis should more and more obscure their training in the humanitarian side of their calling.

The Need for Accuracy and Uniformity in the Reports of Hospitals.—Prof. Frederick A. Cleveland, School of Commerce, read this paper. He said that applying to the problem of administration the nomenclature of medical science one might regard the hospital as having its own habitat, its anatomy, its physiology, and its pathology. Anatomically the hospital was a form of corporate body that through centuries of adaptation had evolved attributes as common in kind as humanity itself, as uniform as the functions of the human body whose physical sufferings the hospital was designed to relieve. The functions common to all hospitals were general administration, professional service, ward service, dietary service, provisioning, housekeeping, laundering, and the general care and maintenance of buildings and hospital equipment. As a medical science could not be developed by the study of the anatomy, physiology, and pathology of a single individual, so administrative knowledge would be small if limited to inquiry with respect to a single institution. Hospital organization and administration had come to be cialized science, the making of which was dependent upon the combined intelligence and experience of all those engaged in this branch of business activity before one could a prominent subject for inquiry, and must become a speestimate such a basis for direction and control as would meet the requirements of men of professional training. By application to well-established standards of efficiency and normality in medical and surgical practice, the superintendent, for example, discovered a symptom of institutional disease in the alcohol bill. Inquiry as to this located the cause in the use of 96 per cent. alcohol for rubbing backs. Another symptom of economic weakness was found in the gauze supply. Administrative diagnosis discovered that the surgeons and physicians were careful, but that antiseptic gauze was being used by the nurses in cases or at times when unsterilized muslin bandages or towels would serve as well. The expense of supplying food seemed abnormal, and this might be traced to a lack of responsibility for supplies, permitting many petty thievery by servants, to the wasteful use of food stuffs, to the serving of high-priced victuals to the house servants, to the purchase of provisions out of season when seasonable ones could have given the same dietetic value, to one or more of a hundred causes. Above all, he said, the administration of an individual hospital depended on the system of control through the accounts. In this hospitals were wofully defective. Like the life insurance company and other trustee institutions, they had failed to appreciate the meaning of administrative control, and the duty of hospital boards to introduce such systems of account which would give it. By way of assembling and transmitting the method and means of collecting and classifying these data around problems of administration a central bureau of hospital research could do much to raise the standard of efficiency. Such an agency would prove especially effective in establishing a form or basis for reporting which could give to the public and to benefactors an intelligent form of hospital trusteeship.

William H. Allen, Esq., Secretary of the Committee on Hospital Needs, opened the discussion. As Secretary of the Committee on Hospital Needs he had been privileged to follow several such discussions as Prof. Cleveland had given. A committee had been appointed after a conference last March, when fifty or sixty hospitals were represented, this meeting having been called because of the press campaign, criticising the hospitals for their lack of proper hospital management. The main objects that

this committee had in view were two in number, first, hospital economy, and, secondly, hospital support. The second object was to him of particular interest. There was no question but that the public was more interested in hospital management than in schools; yet the schools were given $30,000,000 a year, while in the hospitals there was a crying deficit each year. He said that a possible explanation was that suggested by Prof. Cleveland, that the hospital reports had not in the past given information such as the public should have, such information which, if put together in one story, he believed, would electrify the public, and not only would adequate support be forthcoming, but quick action as well. He emphasized the fact that better reports should be published by all the hospitals; they could not expect adequate support until adequate information as to what the public wished to know was furnished. Some form of report should be adopted which would place this serious matter before the public in the proper light if they wished to have intelligent constructive action. When this committee sent out their circular, recommending uniformity of reports, letters were received from all over the United States, showing a quick appreciation of the needs for hospital reform.

Dr. C. Irving Fisher, Superintendent Presbyterian Hospital, after speaking of the manner in which hospital reports were made up, told of the work being done by the Hospital Superintendents' Association of the United States and Canada; in this association the question of bringing about uniformity in hospital reports had been considered at several meetings. At the last meeting in September a scheme had been presented by which reports might be gotten up with uniformity, and a consideration of this, he said, would be continued next year. This winter four hospitals had been brought together in a way that something had been accomplished. Within ten days there had been two meetings of the trustees and superintendents of New York, Roosevelt, Presbyterian, and St. Luke's hospitals, and a practical outline had been agreed upon and was now being printed, which, he hoped, would be adopted. These hospitals, in their next annual reports, would present statistics in a uniform manner.

Dr. Gerster said that his object in bringing this matter before the public was not so much to advocate this or that plan of reform and retrenchment as to excite an interest and discussion of hospital management. He had no plan to advocate, but he did want to excite a general interest and a desire to get at the bottom of the question and investigate why the hospitals were laboring under such tremendous deficits. The public was more interested in hospitals than it was in the schools, yet not enough money could be raised to run the hospitals. It seemed quite paradoxical that public interest should be so well shown in the giving of large moneys to schools, and so little to hospitals, when it was far more interested in the latter. Hospitals were for the purpose of not only curing patients, but also for the purpose of teaching how to cure those not in the hospitals, and he recalled the time when hospitals refused to admit to the wards medical students. One of the most important functions of hospitals was education of medical men. Reform could not be brought about unless the defects were recognized; when discovered, he advised striking at them and without fear. Look for the causes of the existence of these defects, and then he advised against shirking disagreeable facts. He emphasized the importance of overcoming the so often seen lack of intensity. Affairs were too often attended to in an easy and haphazard way. Dr. Gerster said he was astonished at hearing advocated rotation of medical service in hospitals; such was always attended with great dissatisfaction. There was a general lack of intensity in both services. Continuity and intensity of work were productive of the best results.

Dr. Goldwater said that a chair of Hospital Administration in medical schools was highly desirable.

Prof. Cleveland said that the establishment of such a chair in schools for medical training was a suggestion he had in mind. It was for the medical fraternity to devise means of getting together hospital cases which would make a bureau of hospital research possible.

Dr. Brannan and Dr. Thompson closed the discussion.

JOINT MEETING OF THE CHICAGO UROLOGICAL AND CHICAGO MEDICAL SOCIETIES.

At this meeting, held January 24, 1906, Dr. Henry G. Anthony read a paper on "Syphilis of the Male Genitourinary Tract." He spoke of the discovery of the *Spirochæta pallida* as the probable cause of syphilis. Syphilis, he said, was a great imitator of other diseases, and when it affected the genitourinary organs, it might closely simulate any of the other diseases which invaded these organs. Physicians were entirely too prone to depend exclusively on the presence of induration in the diagnosis of chancre. They did not consider sufficiently other points, such as outline, color, smoothness of the base, varnished appearance, etc. For years it had been recognized that it was at times impossible to differentiate between chancre and chancroid. The diagnosis of chancre from epithelioma of the penis was at times difficult. Cases had been observed of patients with lesions of the penis which had been diagnosed epithelioma, the penis amputated, and shortly afterwards the secondary eruption had appeared. When lichen planus occurred on the integument of the genitals, it was apt to assume a circinate form, in which case it was almost certain to be mistaken for syphilis by the general practitioner. Syphilis of the testicle in infancy frequently terminated in atrophy. There were two forms of syphilis of the testicle in adult life—sclerosis and gumma. In gumma of the testicle one or both organs might be affected; there might be a single gumma present or a number. Traumatism might be the exciting cause. In one of the author's cases the patient fell downstairs and struck his testicle against the newel post. As to syphilis of the epididymis, in the early months of infection six or eight nodules might suddenly develop in the upper head of each side. Later in the disease it might assume the form of a simple inflammation with deposits of plastic material, and disappear under treatment, leaving fibrous tissue. Cases of gumma of the cord have been reported by Campbell, Goldenberg, Verneuil, and others. The author discussed scleroderma of the meatus, papular syphilide of the meatus, gumma of the prepuce, cylindroid of the uretha, syphilis of the ureter, syphilis of the kidney, and syphilis hereditaria tarda.

Dr. Alexander Hugh Ferguson followed with a paper on "Tuberculosis of the Male Genital Tract." He discussed tuberculosis of the male urethra, prostate gland, seminal vesicles, vas deferens, epididymis, and testicles. In over one hundred cases of prostatectomy he had observed tuberculous foci in five cases where tuberculosis was not diagnosed before operation, and only suspected in the last two on account of their clinical history. He performed a prostatectomy on three cases suffering from tuberculosis of the prostate in what he judged to be an early stage of the disease. Two died of general tuberculosis within a year; the other lived a year and a half; then died of a bilateral kidney tuberculosis.

Dr. Arthur Dean Bevan said there were three common foci of so-called primary tuberculosis of the genitourinary organs. The term primary should be qualified, although the possibility of a true primary tuberculosis of these organs must be admitted in the sense that the bacilli might gain entrance to the circulation without having lodged at a point where the primary focus was developed, and were carried to the kidney or to the epididymis. Such a true primary involvement was rare. In almost all cases of tuberculosis of the genitourinary organs we had a bronchial or tracheal gland, or some lung or bone tuberculosis which was the primary focus. From this there was

entrance into the circulation of the tubercle bacilli and then their lodgment in the elbow joint, knee joint, or at one or several points, and these points were the kidney, prostate, epididymis, etc. He believed that tuberculosis of the kidney was unilateral in 90 per cent. of the cases, and in these a nephrectomy should be done.

Dr. F. Kreisel was not inclined to be so pessimistic with regard to the treatment of tuberculosis of the bladder. He thought the removal of the kidney, which was the primary focus, might effect a cure of the secondary lesion in the bladder without any other treatment. He did not think that the primary lesion in the bladder could be favorably influenced by applications of iodoform, bichloride solution, etc., so that healing would take place.

Dr. Gustav Kolischer referred to tuberculosis cystitis, and said around the uretheral opening there might be a few disseminated ulcers with undermined edges and a few gray tuberculous nodules. In such cases favorable results were obtained if the kidney which caused the descending tuberculosis, was removed. Rosen had recommended the injection of a five per cent. carbolic acid solution into such a bladder after the kidney was removed, which was followed by disappearance of the ulcers. The speaker removed the kidney of a young girl in whose bladder there were three ulcers. These healed inside of three days after the operation; but whether their healing was due to the injection of the carbolic acid or to the removal of the kidney, he did not know.

Dr. Ferguson, in support of what Dr. Bevan had said, stated that he had done nephrotomy in twelve cases, but had to remove the kidney later. He had two cases now under observation in which he thought a partial nephrectomy was indicated.

Dr. Bevan emphasized the point that tuberculosis of the kidney very frequently was primarily unilateral; and that nephrotomy and resection could not be relied on; that the weight of evidence, where an early diagnosis was made, and the existence of another healthy kidney determined, was in favor of a radical operation.

Chicago Medical Society.

At a meeting held January 31, 1906, Dr. Alfred C. Croftan read a paper entitled "An Analytical Study of Uremia," in which he presented some general considerations and conclusions in regard to its causes and treatment. In the case of the nitrogen bodies the following statements approximately summarized what had been discovered: (1) Uremia often developed without any determinable accumulation of nitrogenous bodies in the blood. (2) Uremia occasionally developed when these bodies were below normal in the blood. (3) Uremia often failed to appear in many states in which the increase of the nitrogenous constituents of the blood was very marked. In the urine similar conditions were found in regard to the nitrogenous bodies. Uremia might occur (1) when the patient was in nitrogenous equilibrium, *i.e.* when the nitrogen intake corresponded to the nitrogen output. (2) When the nitrogen output was far above normal, and (3) when the nitrogen output was below normal as compared to the nitrogen intake. A summary of the findings in regard to the salts of the blood and urine in uremia was as follows: (*a*) An increase of the salts of the blood was by no means a constant finding in uremia. (*b*) Uremia often occurred when the salt values of the blood were normal or even under normal, with corresponding conditions in the urine. (*c*) Uremia did not always occur when the salts of the blood were very markedly increased, and those of the urine correspondingly decreased. There was in fact less evidence to show that uremia was due to salt retention than to the retention of nitrogenous bodies. As to the general principles governing the treatment of uremia, the chief object of treatment should be to prevent the development of acute uremia by giving attention to those organs and functions that threaten to fail. In order to do this intelligently, the renal idea should be relegated to the background, and more attention should be bestowed in preuremic states on the liver and the general metabolism. The liver should have a rest. To stimulate the liver in chronic uremia is bad practice. The same principles should obtain here as in the treatment of a fatigued part or a fatigued stomach or a fatigued nervous system. First, rest, then graduated exercise until the normal tone was regained. Stimulation should be reserved for emergencies and as a last resort. To accomplish this end all articles should at first be eliminated from the diet that can irritate the liver or stimulate it to increased functional activity. Every effort should be made to reduce intestinal putrefaction to a minimum, for intestinal toxins as they reach the liver severely strain the disintoxicating function of the organ. No cholagogues should be administered. After a period of rest (and starvation for a few days seemed a rational plan) the liver might be gently stimulated in the hope that it might be coaxed gradually to resume its functions. This should be attempted by the carefully graded administration of salicylates, of bile acids, possibly of calomel. In addition, various dietetic and physical means might be adopted that were capable of stimulating the various functions of the liver. All this treatment should be carried on with careful supervision and daily control of the effect of these measures on the functional activities of the liver, as evidenced by the composition of the stools and the urine, and the general condition of the patient. The treatment of the acute uremic attack was always an ungrateful task, for it was immaterial whether we were dealing with a disorder that was primarily or in its ultimate consequences due to renal or hepatic or general metabolic insufficiency; in any case we were dealing with a terminal syndrome, that was due to the crumbling of the whole cellular edifice. To arrest this collapse, essentially meant to revive a dying organism. That this might occasionally be done for the time could not be denied, and as the recuperative powers of the human body bordered on the phenomenal, no effort should be spared to bring an acutely uremic patient back to life. We were dealing in uremia with a toxemia, and to eliminate some of the poisons that were present in the blood by bleeding was always indicated. Whether the injection of a saline to replace the lost fluid was useful or necessary was not yet established; it could certainly do no harm, particularly if some saline was injected that would simulate the hepatic function, *e.g.* salicylate of soda in normal salt, or a solution of sodium citrate or phosphate in appropriate molecular concentration. Symptomatically, the use of such infusions had been useful in the author's hands, and had occasionally caused the most alarming symptoms of uremic attack to disappear when other measures he thought would have failed.

Note on a Case of Osteogenesis Imperfecta (Idiopathic Osteopsathyrosis).—J. S. Fowler declares that we owe our knowledge of the condition called osteogenesis imperfecta almost entirely to studies of fetuses, most of which have been still-born, only a few having survived birth for a few hours or days. It has therefore been generally assumed that this condition is incompatible with long life. The writer believes, however, that this is not so, but that children suffering from osteogenesis imperfecta may not only survive birth but reach adult life. He relates the history of a case of this kind. The child at the time of writing was three years old. From his study of this condition the writer concludes that: Children suffering from osteogenesis imperfecta may survive; the condition is recognizable clinically by the association of brittleness of the bones and craniotabes; osteogenesis imperfecta and idiopathic fragilitas ossium are two names for the same disease. The writer thinks that the most conclusive evidence of the identity of the two diseases is afforded by Looser's recent study of the morbid anatomy of idiopathic osteopsathyrosis.—*The Edinburgh Medical Journal.*

*No reciprocity recognized by these States.

†Applicants should in every case write to the secretary for latest details regarding the examination in any particular State.

Massachusetts.—From the Twelfth Annual Report of the Massachusetts Board of Registration in Medicine, we learn that at the July examinations last year the same questions were asked by the Examining Boards in Connecticut, Maine, Massachusetts, and Rhode Island. The percentage of failures in Connecticut was 14.81; in Massachusetts, 15.60; in Rhode Island, 15.15. The Maine results were not reported. It may be inferred that the standard in these States is practically the same.

Idaho.—In this State, recently, a judge reexamined and regraded the papers of a candidate who had been rejected by the State Board of Medical Examiners. This legal luminary raised the applicant's rating from 56 to 69 and set aside the subject of pathology entirely, as being "a subject that only specialists are expected to be conversant with." Students and practitioners who are shaky on pathology (or any other subject) should find this State the ideal one in which to take a State board examination.

Reciprocity Between New York and New Jersey.—The Acting Secretary of the New Jersey State Board of Medical Examiners informs us that the agreement between the two States is retroactive, in so far as it applies to licentiates of New York who have taken the examinations before the New York Board and meet the other requirements of the New Jersey Board. This ruling does not include the older practitioners who have not passed an examination before a duly constituted State Medical Board.

Colorado.—Candidates for a license to practise medicine in this State begin with an oral and a clinical examination. If this proves satisfactory the candidate is then admitted to a written examination. If the candidate fails in the oral and clinical examination, no further test is made, and he is refused a license.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week ending March 10, 1906.

	Cases	Deaths
Measles	2384	55
Diphtheria and Croup	436	62
Scarlet Fever	250	13
Smallpox	.....	.....
Chickenpox	171	.....
Tuberculosis	414	187
Typhoid Fever	17	3
Cerebrospinal Meningitis	30	25
Typhus Fever	.....	.....
Yellow Fever	.....	.....
Cholera	.....	.....
Totals	3,702	345

A Case of Typhoid Gangrene.—Bruhl reports this case. The patient was a young girl, who in the course of a siege of typhoid fever of moderate severity, developed an obliterating arteritis of the popliteal with gangrene of the leg, which necessitated amputation. The obliteration of the popliteal artery was complete, the three coats being involved. There was at the same time a thrombophlebitis. In his report, Bruhl spoke of the relative rarity of gangrene of the extremities during the course of typhoid fever, and the relative frequency of gangrene in children and in adolescents.—*Gazette des Hôpitaux Civils et Militaires.*

Health Reports.—The following cases of smallpox, yellow fever, cholera, and plague, have been reported to the Surgeon General, Public Health and Marine Hospital Service for the week ending March 10, 1906.

THE MODERN TREATMENT OF FRACTURES.*

By CARL BECK, M.D.,

NEW YORK.

PROFESSOR OF SURGERY IN THE NEW YORK POSTGRADUATE MEDICAL SCHOOL AND HOSPITAL, VISITING SURGEON TO THE ST. MARK'S HOSPITAL AND THE GERMAN POLIKLINIK, CONSULTING SURGEON TO THE PHILANTHROPIC HOSPITAL.

It can no longer be denied that the Roentgen method has given a new clearness and a wider range to our diagnostic views, especially in the case of fractures. As a natural consequence our therapeutic means have not only become more simple, but also much more definite. The success of those who still imagine that they can do as well by their happy combination of specially developed palpatory talent with large experience (their results always being good enough for them, even if the wrist cannot be bent or the patient limps and has "only" two inches shortening) will not alter these enjoyable facts. Even these obstructionists gain daily benefit from the new practice, though indirectly and without knowing it. By means of the wonderful rays our methods of treating fractures have in fact become so perfected that with a few exceptions we may say that the plan of treatment can be outlined with almost mathematical precision. The skiagraph suggests it, so to say. The surgeon ceases to be the slave of the manifold more or less complicated splints. All he needs is a detailed diagnosis, which dictates the method of reduction as well as that of the immobilization.

"Qui bene diagnoscit, bene medebitur" applies preeminently to the treatment of fractures. A textbook on the treatment of fractures cannot contain too many diagnostic points, therefore, while the details of practical therapy can, under the new perspective, be printed on a few pages, or according to great Hippocrates, be written on our finger-nail, so to speak.

It is admitted by the best authorities now that there is an enormous number of bone injuries, the character of which could formerly not be recognized on account of the swelling of the area involved, or of the obscurity of the symptoms. Fractures were mistaken for dislocations, contusions, or distortions, and vice versa, for the reason that the main symptoms, viz., local pain and swelling, are common to all these injuries. In fissures and nondisplaced or impacted fractures crepitus and false motion are generally absent. Now the differential diagnosis may be made by a simple glance with the fluoroscope. Whether there is comminution, impaction, or intervention of tissue can be just as clearly determined as the question whether the fracture is of the intraarticular type, or is associated with dislocation or other complications.

In a number of nondisplaced fractures considerable effusion takes place, especially if they are of the intraarticular type. The clinical expression of this condition is a swelling of the fractured area, which in most cases suggests the presence of displacement. Naturally the surgeon would be tempted then to make reducing manipulations, which would be most harmful to the patient because they would cause the very thing which he would like to avoid, viz., displacement. Now, the Roentgen rays penetrate any amount of effusion and will therefore tell us precisely whether manipulations are necessary or not. In other words, if no displacement is shown, all that is required is to protect the injured limb in its normal position. This is done by proper immobilization. I personally prefer the plaster-of-Paris dressing, because it adapts itself to any shape of the body in a most admirable manner, and permits, furthermore, of continuous control by the Roentgen method, since its material offers no obstacle to the rays.

If there is more or less displacement, the fragments must be reduced to where they had been before, that is to their normal position. After exact position has been attained, proper fixation in the normal position is in order.

These doctrines are so extremely simple, that it seems almost unnecessary to repeat them. Yet they are frequently violated.

The functional impairment following non-reduced fractures, especially through the formation of adhesions, has led a number of surgeons to enunciate the dogma that the treatment of the soft tissues is the most important part of the treatment of fractures. They claim, in other words, that because the function of the soft tissues, for instance of the tendons, is impaired after an unreduced fracture, the soft tissues should have received more attention, instead of the displaced fragment having been simply reduced to where it belongs. Nothing, in fact, is more contrary to common sense than this dangerous maxim, which is partially based upon correct observation, but entirely upon incorrect interpretation. It should always be considered that the relations of the soft tissues to the bones are like those of the clinging vine to the sturdy oak.

Galen says that the bones give the human body form, erectness, and firmness. It is evident that an injury to the bones impairs these three fundamental factors. The most important step toward repair must thus be taken in the foundations rather than in the superimposed structures.

If there is displacement of the bone fragments, undue pressure must necessarily be made upon the soft tissues; non-reduction means persistence of pressure, the fatal consequences of which are well known. Reduction means the relief of pressure. If, for instance, in the frequent fracture of the carpal end of the radius the lower fragment is displaced upward, the extensors are unduly stretched, as they are upheld like the strings of a violin by the bridge. Of course, the act of the injury to the soft tissues cannot be undone by the mere cessation of pressure

*Presidential Address delivered before the Society of Medical Jurisprudence, January 8, 1906.

—that is by reduction—but the influence of the injury on the soft tissues is insignificant after early reduction, and therefore repair is easy. This means that there is hardly any more inflammatory irritation; in other words, the main premise of adhesion—formation—is wanting. Clinical observation shows that with perfect reposition the joints as well as the

Fig. 1.—Malunion in upward and lateral displacement; three months after fracture of the lower end of the radius.

sheaths of the tendons are found free, provided the immobilization has not lasted for an extraordinary length of time.

A fracture is a solution in the continuity of bone, just as a wound is a solution in the continuity of the tissues in general. The aim of modern wound treatment is union by first intention. The most important requirement for this end is, besides aseptic precautions, the thorough adaptation of the wound surfaces.

No surgeon would expect agglutination if there were displacement, diastasis, or overlapping of the wound margins. The same principle applies to the treatment of the margins of the bone fragments. It is true that manual coaptation is a little more difficult than suturing; still, under the guidance of the Roentgen rays it can be accomplished if there are no extraordinary circumstances. Before their advent it was usually the final result alone which told of the success or failure of treatment. That result was then a *fait accompli*, and the time for proper correction had passed. Now, with our Roentgen-light mentor we can tell from the very beginning what the result will be. If the "Roentgen-mirror" reflects perfect coaptation of the fragments underneath the dressing, the final result must be good. There will be hardly any reaction; no exudation will form around the agglutinating surfaces, and consequently there will be no adhesion. Even in many cases in which considerable displacement, or comminution, or both, has injured the soft tissues, little reaction follows within them, if reduction be thorough. And if reduction is impossible, the Roentgen rays tell us so precisely, giving a chance for early operative interference. They point to those fragments at the same time which are to be removed shortly after the injury. This is preferable to waiting for months, exhausting all mechanical means, and finally arriving at the conclusion that the deforming fragments had better be removed. What many of us have in former years regarded as callus was nothing but a projecting piece of bone-fragment in a displaced position. It may, perhaps, be a pardonable policy to adhere to this most euphonic term in the presence of the inquisitive and criticising patient, who has a dangerous desire to learn the cause of the gibbous joint. But a scientific forum cannot ignore this frequent failure to reduce.

The regular scar of a well-united wound must be the model of our therapeutic efforts. Direct union is to be striven for. What is termed ensheathing callus-formation means union by second intention; this is certainly undesirable as long as union *per primam* can be well accomplished. Ensheathing callus is the compensating effort of nature to overcome the unreduced deformity and to bridge over the hiatus made by irregular adaptation.

I am well aware of the fact that a slight protrusion of a diaphyseal fragment would ordinarily not disturb the function of the limb. In fact we meet with extensive diaphyseal displacements sometimes which did not interfere with the free use of the limb. The experienced surgeon must instinctively know what allowances he can make. But in fractures affecting a joint it must be emphasized that even small projections may seriously interfere with the function.

In order to accomplish exact reposition, the degree and the direction of the displacement, as it is shown by the Roentgen ray, must first be considered. It is true that an experienced surgeon will often guess right, but he will never know, except by his infallible adjunct, the Roentgen rays. The only safe method is the self-control by the Roentgen rays. It may appear to be unjust to demand of the struggling practitioner that he should supply himself with an expensive Roentgen apparatus, or if he does not care to take the trouble himself, to trust a more energetic fellow-practitioner. But after all there will hardly be any other choice. The public is cruel, and the patient's interest concentrates itself almost entirely in his own welfare, while that of his surgeon bothers him but little. He does not consider what difficulties the average practitioner has to struggle with, and how well he does, as a whole, in spite of so

Fig. 2.—Deformity in fracture illustrated by skiagraph (Fig. 1).

many adverse circumstances. All he considers is his deformity, and it is his physician, and his physician only, whom he blames without any appreciation for adverse circumstances. He does not realize that there may have been an intraarticular or comminuted fracture. His narrow horizon brings his case in contrast with the case of his neighbor who was

treated with a better result by a simple "bone-setter." Of course, his may have been a comminuted joint-fracture, while the quack's was a non-displaced simple fracture, which, in fact, healed rather in spite than because of the treatment.

In a country of such rich resources, however, it should not be difficult to secure proper means from

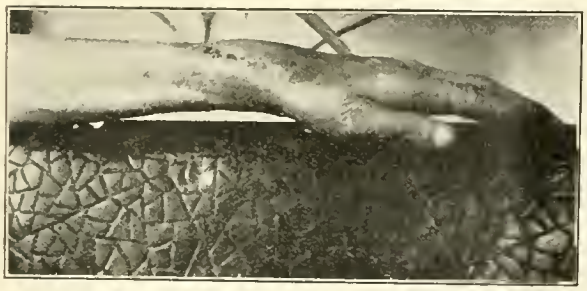

Fig. 3.—Hand illustrated in Figs. 1 and 2, after correction of the deformity by the chisel.

the government to establish Roentgen institutions, where worthy patients could be skiagraphed free of charge. Thus the practitioner could get the same reliable information he obtains from the Health Department to-day in cases of suspected infection.

If the displacement is recognized and the principles of immediate reduction are adhered to, the "gibbous wrist" will cease to be counted among the inevitable inventory of surgical clinics. Still, I am afraid this is a pious wish so long as there are surgeons who imagine that they can judge the details of any fracture without the aid of the Roentgen rays. Some are willing to use them in "obscure" cases, but they do not realize that the cases which they regard as "non-obscure" would appear in a different light when skiagraphed. In other words, what they regard to be a simple fracture often turns out to be a complicated condition. The paradox may be justified here, that if they would see this complicated condition in its proper light they would be very much surprised by it, and it would then seem obscure to them.

As said above, if there is no displacement, no effort of reposition should be made. How absurd, then, to subject the patient, as is often done, to painful procedures. In simple fissure, union may be perfect, under any or in spite of any, form of treatment. If the surgeon, led by anatomical knowledge, does practically the same as the quack does on account of his ignorance—namely, leaving the healing process to nature—the same good result may finally be obtained. The scientific treatment of fissure or non-displaced fracture, in which portions of the periosteum, still maintain slight cohesion of the fragments, viz., slight immobilization, will not alter any of its mechanism, but it will at least have the value of a greater or lesser comfort for the patient; and in cases of this kind we must be warned against scientific nihilism.

If the displacement is detected not more than two weeks after it was sustained, refracture under anesthesia is generally successful. Then the same condition is virtually produced which existed at the time of the injury and the maneuver of reposition is done after the same principles as explained above. Sometimes refracture is possible even after six weeks. But this is an exception and applies, as a rule, to diaphyses only. I present two cases in which refracture was entirely successful, although there was extreme displacement. The one case is that of a woman of fifty-eight years, whose lower radial end became agglutinated in the classical silver fork position, refracture being done without anesthesia at the edge of the table; the other is that of a boy of twelve years who sustained an epiphyseal separation of the lower end of the radius, associated with transverse fracture of the lower end of the ulna. There was considerable ulnar protrusion (outward displacement). Refracture and inward reposition were undertaken under anesthesia, also with a good result. After the proper time for bloodless refracture has passed the deformed area must be exposed by the scalpel. The old fracture line will be divided so that just as in the bloodless method the same situation is created which had prevailed at the time of the injury. The division is done by a thin and broad chisel, after the periosteum is carefully lifted all around the bone. The surrounding tissues are retracted by spoonlike retractors. The opposite surface is also protected by pushing a spoonlike instrument underneath (compare abdominal spoon, illustrated in the Medical Record, February 4, 1905). If there is no tendency to displacement the soft tissues are united and a fenestrated plaster-of-Paris dressing applied.

As an illustration Figs. 1, 2, and 3 may serve to represent the vicious union of the lower radial ends in a man of fifty-eight years, three months after the injury. Fig. 1 shows the silver fork deformity by

Fig. 4.—Periosteal Proliferation three months after a fracture of the radius.

the rays, while Fig. 2 depicts the upward and sideward displacement as it could be seen by simple inspection. After the old fracture line was divided by the chisel a slight downward pressure with my thumb sufficed to place the fragment in position. Fig. 3 indicates the normal position of the hand three weeks after the operation. It shows the in-

cision line alongside the "Tabatière", which seems to me to be the most accessible portion for this operation.

If there is great tendency to displacement, as we find it especially in such bones which are not provided with a good periosteal coat, suturing with bronze wire is indicated. This is an absolutely reliable material. As to operative details, see my previous publications "Ueber deform geheilte Frakturen und ihre Behandlung" (*Münchener medizinische Wochenschrift*), November 17, 1901, and "The Operative Treatment of Deformed Fractures as Indicated by the Roentgen Rays" (*New York Medical Journal, December 27, 1902*).

Fig. 5.—Sarcoma of the head of the humerus, originally mistaken for fracture of the shoulder.

In order to prove my statement that we are easily liable to err in our detailed diagnoses, I have asked a dozen of my patients, mostly under my treatment yet, to present themselves to you. In none of them have I been able to make a detailed diagnosis without the aid of the Roentgen method.

In a few of them I had to change the views held on the basis of my palpatory findings, in others I had to modify them. In some of the patients the method enabled me to detect conditions which threw new light upon some pathological changes. So, for instance, did it clear up some peculiar phenomena caused by the injury of the periosteum in one of the cases.

We all appreciate that one of the natural mechanical results of the solution of the continuity of bone is the more or less extensive tearing of the periosteum. We may imagine that small periosteal shreds are scattered around the area of fracture. During the process of healing these particles of periosteum begin to proliferate in the sense of an ossifying periostitis, until finally they produce the external or periosteal callus.

Small platelets of bone which have been ripped off from the cortex are found in those cases in which a great amount of force was exerted, and where a decided dislocation of the bone fragments exists. At times we find minute fragments of bone which are placed at such distance from the point of fracture that all connection between it and the bone itself seems severed. The general consensus of opinion has seemed to be that these loosened particles become impaled in the soft tissues and acquire their nutrition from them. During the past I myself have believed in this theory, but skiagraph No. 4 has shaken my belief. As I study it I must come to the conclusion that in many similar cases periosteal bands exist, but are of such flimsy construction that they are, as a rule, overlooked. They convey the nutrition to these displaced and fractured fragments. On the skiagraph, taken five weeks after the injury, may be seen, running from the upper radial fragment, a band of periosteum about five inches long. I might compare it with a sheet of bark which has been stripped from a green tree still adhering at the base. In spite of the extensive injury a loosening only, not a tearing, of the periosteum has been caused. The picture, taken by Dr. Eric C. Beck, distinctly portrays the conditions. The case as illustrated by the skiagraph is surely one of greater frequency than we suspect. Unless the technique is a perfect one the result will be that the bones are too vigorously irradiated, and the more delicate periosteal bands will be outshone.

Fig. 6.—Double fracture of the patella.

The more recent the injury, the greater the liability of error. The picture also demonstrates the

difficulty of reposition. The patient being anesthetized, I twisted the ulna. Having noticed a perceptible outward rotation of the lower radial fragment, I felt assured of apposition. While the assistant pressed the ulna inward by means of a bandage loop, I applied a plaster-of-Paris dressing. A skiagraph was taken immediately after. The plate showed that the method adopted had not been successful, and I took off the cast to apply a second one. The result was a better one. Though the function of rotation is good, yet the bones are not in exact position. I wish to remark that the periosteal band followed the upper fragment, and that considerable callus which has formed upon it can be seen, although the skiagraph was taken through the plaster cast. I am glad to say that the skiagraphic conditions, as demonstrated, were stronger than my power of persuasion, the patient submitting to operation—indentation without wiring—shortly after the presentation. The result was perfect, the periosteal band, however, being still noticeable five weeks after the operation.

The importance of the question of periosteal dislocation is also proven by the case of a young man who sustained a fracture of the humerus. Due to the extensive dislocation of the fragments the periosteum was loosened from the bone over a wide area. After covering the fragments this grew to such an extent that it became an obstruction. I removed it subsequently, thinking it might influence the action of the muscles. This teaches us to think of this possibility in cases of suturing of bone, and makes it advisable to remove all miniature fragments and such portions of the periosteum as protrude beyond the point of fracture. If not done, the process of healing may simulate disease.

In this wise the wonderful rays time and again produce new impressions, by the study of which we gain an ever-increasing knowledge concerning the internal mechanism of the healing of bone injuries.

Similar unexpected knowledge was obtained in the case of a man of twenty-nine years, who presented himself at the Postgraduate Hospital with the history of an injury sustained by being thrown down in the street by a trolley car. Pain and disturbance of function followed. Inspection did not reveal any swelling of the shoulder, while palpation disclosed pain and tenderness, while motion showed the presence of crepitus. The Roentgen method (diaphragm) detected the presence of sarcoma of the head of the humerus, which explained the symptoms, especially the fact that a comparatively small amount of violence should have produced a fracture (Fig. 5). Of course, the thin bone shell left by the osteosarcoma would break easily. The patient denies having had any pain or disturbance of function before the accident. This statement I looked upon with diffidence, because the patient expressed the desire of bringing suit against the car company. After the true facts were disclosed to the patient he kept away from the clinic.

This is a case of early recognition of osteosarcoma, the accident furnishing the chance for thorough examination before marked signs would have induced the patient to seek surgical aid. In a case of this kind early resection, followed by Roentgen therapy, would make the prognosis more favorable. The medicolegal importance of the circumstances accompanying the case is self-evident. The skiagraph is a protecting document for the surgeon in the first place. Suppose amputation would have been attempted later without resorting to a Roentgen examination first, the surgeon who first treated the "fracture" might have been held responsible. In the second place the Roentgen knowledge of the case would protect the company against an unjust claim.

To illustrate my views in general, especially with reference to the indications and the technic of operative interference, I may select the patella as a paradigm. The patella is a small bone which, by its superficial location, should appear to be easily accessible to palpation. But my cases demonstrate how even in so pregnant an instance we are apt to err. On account of the absence of a proper periosteal coat, the patella, being a true sesamoid, has little tendency to osseous regeneration. How intrinsic the influence of the periosteum is, we have been able to study well in Fig. 4. It is self-evident therefrom that unless the fragments are well approximated, osseous union cannot take place. And experience has shown that there is no dressing which affords perfect coaptation by any bloodless method; the intraarticular effusion following the fracture always keeping the fragments more or less separated. Still more, it must be borne in mind that the contraction of the extensor muscles always severs the fragments again, even though they have been brought into apposition. The intrusion of soft tissues, a frequent occurrence, is also an important factor in preventing perfect coaptation. The irregular character of the osseous tear is responsible for the laceration of the adjacent tissues, especially ligamentous structures, which become interposed in the gap.

Aspiration of the effused blood has often been tried, but the large clots situated behind the injured area in the joint cavity cannot be driven into the aspirating needle.

The rays have furthermore, as in similar injuries, revealed the fact that there is much more displacement of the fragments than we anticipate, by virtue of our palpating examination. Naturally we must stumble in our diagnosis, and how much greater must be our shortcoming in therapy? Here also the Roentgen method is a friend and truth teller. It shows that not in a single instance is the reduction thorough, even under anesthesia. The fragments diverge invariably, the upper fragment either being pulled upward by the quadriceps muscle, or the lower fragment being completely turned, since the lower patellar ligament has lost its power of contraction.

The recognition of all these well-proved facts shows that the only rational remedy consists in the opening of the joint, its thorough evacuation, and the suturing of the fragments, and eventually wiring. In cases treated by the "bloodless or so-called conservative method," the function of the joint is always impaired in ability to perform extension and thorough flexion, considerable atrophy of the muscles and greater or lesser degree of knock-knee being the predominating symptoms. While those patients who follow a light occupation may not be incapaciated, and can carry their burden with the aid of a knee-cap, working men are deprived of their means of making a living by not possessing the full use of their limb.

The integumental incision is given a semilunar shape, so that a flap is formed, the convexity of which touches the lower border of the patella. The flap is then reverted in the upward direction, the coagula and loose shreds of tissue are removed, and the joint is irrigated with hot salt solution. Any intervening tissue, small bone splinters, and similar fragments are to be evacuated; their nutrition, on account of their scanty provision of periosteum, be-

ing greatly impaired, it is generally impossible to preserve them. Everything, in a word, that stands in the way of exact apposition, should be removed. For uniting the fragments I use catgut if the soft tissues can be well appositioned. If not, I prefer a bronze suture of medium thickness. This material

Fig. 7.—Old patellar fracture wired.

is preferable to any other because its soft elasticity permits of thorough twisting without the risk of a break. The holes are bored in an oblique direction by means of a metal bone drill, while each individual fragment is firmly grasped by a bone-holding forceps and held upward while the manipulations are going on. Through a small slit, made in the middle of the flap, the ends of the wire are drawn out and bent over a small wick of iodoform gauze. Four to six weeks after the operation they are to be extracted. One bronze suture is sufficient if the twisting is done thoroughly. But the soft tissues must be united with the most minute care. Especially the lacerated portion of the capsule and ligaments must be carefully united with catgut. The whole extremity is then to be enveloped by a plaster of Paris dressing, reaching from the foot up to the pelvis, and provided with a fenestra for the control of the wound-area. Thorough asepsis is, of course, the *conditio sine qua non*. Cotton gloves are worn by the surgeon, as well as by his assistants, and grasping the tissues with the hands is avoided as much as possible. No joint reacts so promptly to the slightest offense given to asepsis, and so deplorably, as the knee joint. The reason must be sought in its peculiar anatomical conditions.

In fresh cases the technic is extremely simple. In older cases plastic manipulations must often be undertaken. Then the bronze wire is absolutely necessary as a support. The thorough refreshing of the fragmental margins must then almost always be undertaken. One case may serve as a type. It is that of a man of twenty-six years who sustained his patellar injury by a fall in May, 1905. The diagnosis of simple transverse fracture was made by a reputable physician, and the extremity immobilized in an extension dressing. Seven weeks afterward the patient was allowed to walk about. While it was possible for him to do some of his work, he could not do it well, and standing on his feet more than an hour made him extremely tired. This induced him to invoke surgical aid. I had the privilege of seeing the case October 15 for the first time. The patient limped slightly. Palpatory examination showed a slight transverse diastasis in the middle of the patella. The impression was that a fibrous but firm union had taken place. But skiagraphic examination (Fig. 6) showed the injury in a much severer light. In the first place the fact was revealed that instead of one fracture line there were two, one being represented by the slightly palpable transverse gap, the other being oblique, running upward to the inner margin of the patella; in other words there were three fragments. Between the upper and middle fragments osseous union had

Fig. 8.—Comminuted fracture of the lower third of the femur.

taken place in a somewhat deformed position, the lower fragment projecting anteriorly. This condition had escaped my notice completely on palpation. Between the two fragments which had seemed as one of us, and the lower a gap of fully an inch was detected. This showed, as did the subsequent

operation also, that most of the gap was filled up with irregular fragments of soft tissue, which palpation had erroneously taken for bone structure. It is needless to say that all these masses had to be carefully extracted before the fragments could be made movable. The osseous union between the two other fragments was not disturbed, but the project-

Fig. 9.—Fracture of the femur (Fig. 8) united by wiring; taken through a plaster-of-Paris dressing.

ing bone portions were equalized with the chisel. After having removed considerable capsular remnants from the posterior margin of the lower fragment, it became possible to approximate it to the upper area, but only at its posterior half, the anterior portion still gaping. Still it could well be fastened with a bronze suture (Fig. 7). The remaining portions of the capsule could also be coaptated, and were united with thin catgut. Five weeks after the operation careful massage was begun through the fenestra, and three weeks later the wire was removed. The patient will no doubt have perfect use of his limb. The skiagraph shows perfect osseous union between the two posterior halves of the sutured fragments. Artificial motion was begun a few days ago. On account of the impossibility of drawing the anterior hiatus together, I deemed it more certain to defer extraction of the wire as well as the beginning of the massage treatment for several weeks.

That there are fractures which cannot be reduced properly by bloodless means, although the greatest amount of care is taken, and although the Roentgen method gave the most precise information also as to the detailed character of the injuries, is proved by cases seven and eight. They illustrate how careful the critic has to be, and they also show how necessary it is that the surgeon secure a Roentgen picture in time, so that he can prove the complicated character of the fracture. I have seen both cases not later than two days after the injury, and I have not been able to accomplish proper reduction under anesthesia. In the first case, that of a woman of forty years, who leaped from a height of one hundred and twenty-five feet into a net, which broke, fracture took place at the lower third of the left femur. There was an overlapping of the fragments to the extent of over three inches (Fig. 8). At the same time a number of larger or smaller splinters had formed. The bloody effusion was enormous on account of the extensive laceration of the muscular vessels. There was considerable contusion of the sacrum at the same time. Even after the fragments were freely exposed from the external side, it was impossible to get them into apposition, although a considerable amount of tension and contraextension was exerted. Only after a large chisel was used as a lever could the contraction of the muscles be overcome. One bronze wire (Fig. 9) kept the fragment well in place. The blood clots, the numerous bone splinters, and the shreds of muscular tissue were removed. Recovery was uninterrupted. The wire was removed eight weeks after the operation. The result is blameless.

Case eight is that of a boy of fourteen years who sustained fractures of the lower ends of both bones

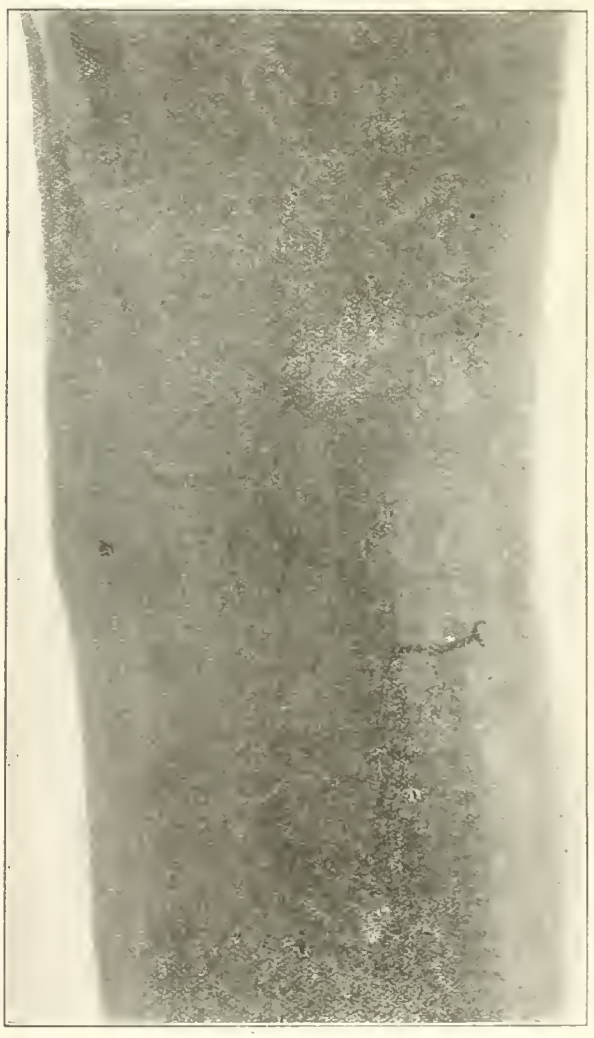

Fig. 10.—Wiring of the radial and ulnar fragments; taken through a plaster-of-Paris cast.

of the left forearm, by a fall on the outstretched hand. The skiagraph revealed extensive displacement of the lower radial and inward displacement of the lower ulnar fragment. I exercised considerable extension and contraextension, and had the impression that the fragments became approximated. While

they were held in that position a plaster-of-Paris dressing was applied. But the skiagraph taken through the cast at once showed my failure. Another attempt was then made under anesthesia, this time the apposition being worse than originally. I learned by this result that the difficulty was offered by my failure of disentangling the lower ulnar fragment. Therefore, after anesthetizing the patient once more, I tried a different maneuver. Instead of extending I tried rotatory manipulation, which should twist the obstinate fragments. But skill was not equal to will. On the testimony of the skiagraph I explained my failure to the patient and suggested exposure of the fragments, disentangling by the chisel and wiring, to which the patient readily consented. Even then, after exposing the ulnar fragment thoroughly, it was only possible to shift it to the opposite side, after repeatedly lifting it over the upper fragment (Fig. 10). Recovery was perfect in six weeks.

Case ten was one in which the lower epiphysis of the humerus detached and completely turned round, so that it became attached to the diaphysis lengthwise. A big mass was felt at the inner surface of the lower portion of the arm. Those who had no chance to examine the arm by the Roentgen method thought this mass, which was nothing but the displaced lower end of the humerus, to be abundant callus. The function of the extremity was inhibited so that the patient, a man of twenty-six years, was unable to make a living. Seven months after the injury I first tried to expose and displace the fragment with a view to transplant it to its normal habitat. But when I had severed it from its connection at the lateral surface of the humerus, I found it to be denuded from tissue, its external surface being represented by the articular surface only. Consequently nutrition would have become greatly disturbed, wherefore I removed it. The result is fairly good, the patient being able to use his arm since the impediment was taken away. The atrophy of the muscles has also disappeared. The arm can be well bent, while extension is possible to an angle of one hundred and fifty degrees only.

I may sum up these views in the following theses:

Let us now consider these cases from a medico-legal point of view. Suppose that the advice given on the basis of the skiagraphs and my tentative manipulations had not been realized. In that case a shortening of three and one-half inches in the first, and a deformed hand, very much impaired in function, would have been the result in the second case. Suppose the patients had then sued me for lack of skill? If I were not in possession of the skiagraphs I am positive that I should not have been able to exonerate myself in court.

I may sum up these views in the following theses:

1. The Roentgen method, in combination with the usual methods of examination, determines the character of a suspected bone injury.

2. If there be no bone injury, the proper treatment consists in massage followed by immobilization, a movable splint being preferable for the latter purpose.

3. If there is a fissure or fracture, followed by no displacement, manipulations of the injured area must be avoided and immobilization in the most comfortable position applied. As a rule a plaster-of-Paris dressing answers the purpose best. After two or three weeks it must be removed and massage begun. In about two weeks a splint of plaster-of-Paris is applied, which the patient can take off and reapply.

4. If there is any displacement, reduction must be tried at once. This can be done either under the control of the fluoroscope on a translucent table, a plaster-of-Paris dressing being applied after reposition is perfect (see Fig. 10 in "The Value of the Roentgen Method in Surgery", *Modern Physicians' Library*, L. Simion Nf., Berlin, 1905). This is a simple, short, and cheap method. A more tedious, but a safer way, is to reduce the displacement under the guidance of a skiagraph taken before. This will indicate in which direction the efforts at reduction must be made and how far. After a plaster-of-Pars dressing, padded with cotton layers at its ends only, is applied, the skiagraph is taken through it, in order to ascertain whether reposition was complete. If it does not seem to be, the dressing must be removed and another attempt at reposition made. If the process of reduction meets with difficulties, an occurrence which can, as a rule, be anticipated from the nature of the skiagraph, anesthesia should be employed.

5. In those cases in which, on account of entangling of the fragments, extensive splinter formation, or similar complications, reposition, even under anesthesia, cannot be accomplished, the fragments must be exposed by the scalpel and brought into apposition. If there be no tendency to displacement, as in the case illustrated by Fig. 1, a plaster-of-Paris dressing will insure immobilization. But if the fragments slip out easily it is safer to unite them with catgut, provided there is enough periosteum to be utilized for that purpose. Otherwise it is best—especially if large bones come into consideration—to keep them together with a bronze wire suture. The sooner this is done, the better it will be, because the smaller are the changes taking place in the soft tissues.

THE UTERUS AND OVARY OF NEURASTHENIA.*

By ROBERT L. DICKINSON, M.D.,

NEW YORK.

GYNECOLOGIST TO THE BROOKLYN HOSPITAL; CONSULTING GYNECOLOGIST TO ST. MARY'S HOSPITAL, JAMAICA; OBSTETRICIAN-IN-CHIEF TO METHODIST-EPISCOPAL HOSPITAL, BROOKLYN.

Summary: This study is restricted to the chronic and aggravated type of neurasthenia, and is based on full histories of a hundred cases.

I. The associated lesions in *cases of this degree*, and their frequency, as indicated by this series, would be as follows: (a) In the ovary, chronic ovaritis, chiefly microscopic, was found in nearly all; (b) in the uterus, endometritis, usually cervical, was present in the majority of cases, and was seldom accompanied with thickening; (c) a high degree of sclerosis of the vessels of the uterine walls, and of those of the endometrium, was sometimes discovered in cases of long standing, and the venous enlargements were many; (d) about the vulva, certain hypertrophies were noted in two-thirds of the cases; (e) in the bladder, congestion of the trigone was frequent (about 40); (f) in the rectum, catarrh, congestion and atony were persistent in a large number.

II. In this class of cases pelvic symptoms are prominent and lumbar pain constant.

III. In almost all of these cases the pelvic disorder is coincident, not causative.

IV. Correction of moderate abnormalities of structure and function by prolonged local treatment or by operation lessens pelvic pain very little and betters the general condition not at all. Treatment should be directed almost entirely to the general condition.

*Read before the Philadelphia Obstetrical Society, December 7, 1905.

V. Operation on pronounced pelvic lesions is warrantable in a few selected cases, such as persistent and exhausting hemorrhages, and the larger tumors, and, if thorough-going, brings about a revolution in the general condition in a very small percentage of cases.

VI. Anatomic cure frequently fails to bring about symptomatic cure.

While the bearings of pelvic disease on hysteria and insanity have been so studied, and the neuroses in general, what is new in this small series of cases is the clinical analysis, from the standpoint of the gynecologist, of the relations of pelvic disease to long-standing neurasthenia; the claim of the frequency of chronic ovarian changes, of chronic congestions of trigone and lower bowel, and of the vulvar hypertrophies of self-abuse; the statement that laterocession of the uterus and thickening of the left uterosacral and broad ligament, with left-sided ovaritis, in the absence of adhesions is always due to chronic proctitis; and figures bearing on the small percentage of cures after operation.

Literature.—There is a great body of writing concerning the interrelationship of insanity and diseases of the pelvic organs, and no small amount bearing on hysteria and pelvic disorders. Anent neurasthenia less has been published, but the general tendency is in one direction.

W. A. Freund ("Neurasthenie Hysterica der Frau," Berlin, 1904, pp. 40; "Das Bindegewebe beim weiblichen Becken, Gynaekologische Klinik," 1885; Gratulations-Schrift für Chrobak, 1903) believes that certain alterations in the connective tissue of the pelvis cause notable anatomical changes in the nervous system in the internal genital organs in women, whence follows a series of constant disturbances in distant organs, as well as peculiar physical changes. One form occurs after acute parametritis, to wit,—scar pressure. The chronic variety is due to long standing catarrh of the bladder, rectum, or cervix, causing scar-like changes in the internal pelvic fascia. The veins are thick-encircled, dilated, or compressed, the arteries narrowed, the ureters drawn upon. The first effect is a venous hyperemia, the last a marked atrophy. He pictures alongside the lower half of the body of the uterus, and alongside the cervix, and beneath the cul-de-sac, extensive neuro-fibromata,—paravesical, parametric, paraproctal. Striking varicosities in the venous system of the vertebral canal and the pia in the sacral and lumbar regions were also found in those women who presented grievous lumbar cord symptoms. Therefore Freund stands for the genital cause of hysteria. He enumerates as causes: Masturbation, excessive coitus, or coitus interruptus, malnutrition, overwork, rapid childbearing and lactation. But he particularly distinguishes women with hypoplasia of the genital and vascular systems, who are condemned to excessive use of the sex function.

F. C. Müller ("Handbuch der Neurasthenie," Leipzig, 1893), under the head of etiology, states that chronic catarrh of the genital passages does not readily set up neurasthenia (as in the male), because the female does not brood over such matters, and associate them with loss of sexuality. Nevertheless, affections of the uterus and adnexa, including uterine displacements, erosion of the portio, and chronic endometritis, are able in themselves to determine not only neurasthenia, but other neuroses and psychoses.

Savill ("Clinical Lectures on Neurasthenia," 2d Ed., N. Y., 1902), under etiology, only speaks of masturbation. This, he believes, to be more common in women than is usually thought.

But the majority of observers are all on one side

Engelhardt ("Zur Genese der nervosen Symptom-Complexe bei anatomischen Veranderungen in den Sexual-Organen," Enke, Stuttgart, 1886, pp. 3, 69), reports on four groups of cases, from Hegar's Freiburg Clinic, many being given in detail—109 cases in all:

1. Marked anatomical changes in the sex organs, *with* lumbar cord symptoms.
2. The same, *without* nerve disturbances
3. Absence of alterations in the sex organs, *with* lumbar cord symptoms, and other nerve disturbances; and.
4. Minor pelvic changes with the above symptoms.

Although two-thirds of his cases are available for comparison, that number includes few that belong in the class of severe cases which I have selected for study;—this is to be borne in mind in reading his conclusions. These are, in part:

"A local pelvic disorder can alone cause nervous manifestations, and often these are confined to the nerves belonging to the lumbar cord. A single distant reflex may be started. Severe widespread neuroses, however, are produced only when such a local disease has been of long standing. Reflex and sequent influence is then rarely alone at fault." Yet it may be the primary and important cause. "To attribute a constitutional neurosis like hysteria to a concrete anatomical alteration contradicts all clinical experience." "In the majority of sufferers from combined sexual and nervous disorders, a very complex set of conditions exists. Congenital predisposition, a tendency acquired in childhood, bad hygiene of puberty, physical injuries, sexual irritations, acute or chronic illness, hard labors, hemorrhages, these damage the nervous system and lead, in combination with the pelvic trouble, to the functional nerve disorder."

A cause which Engelhardt's observations develop is coitus imperfectus and onanism. "We are obliged to maintain that the very severe neuroses which develop (hysteria, with epileptiform seizures, asthenopia, etc.), as well as the pronounced cystic degeneration of the ovaries, with slight perioophoritis,—that these are coeffects of the unnatural irritation of the peripheral genital nerves and of the psychic excitation."

In Engelhardt's cases, one without knowledge of the cause can hardly doubt the primary affection of the nerve center. Unhappily, the conditions are not so simple as this. The symptoms permit of the supposition that a peripheral origin exists. Changes in the sex organs exist, but may be secondary. A fair proportion of Engelhardt's cases do not exhibit nervous symptoms and dysmenorrhea until late in their history. Exhaustion from difficult labors and overwork are then combined with serious pelvic trouble.

Grasset and Rauzier ("Traité Pratique des Maladies du Système Nerveux," 1894).—Under the head of *surménage genital* as a cause of neurasthenia, the authors suggest that masturbation may be an effect rather than a cause, *i. e.* there is no certain way of differentiating between cause and effect. They quote Charcot's distinction between psychical and organic neurasthenia. The latter may proceed from the stomach, liver, genitals, etc.

Löwenfeld ("Pathologie und Therapie der Neu-

rasthenie und Hysterie," 1894; on page 71, summary of views of relations between Neurasthenia and Genital Lesions): 1. Sexual lesions are in themselves sufficient to determine nervous disturbances. The former comprise flexion, prolapse, catarrh, and chronic endometritis and ovaritis. As a rule, there is a neuropathic predisposition. As for the mechanism, the nervous disturbances are in part, of reflex origin, due to compression of the local nerve filaments, in part due to losses of blood and pus, etc., and finally, in part, due to brooding over the disease. 2. Other causal factors usually coexist. 3. The two conditions represent a mere coincidence. 4. A woman already neurasthenic may become worse as a result of some genital lesion or disorder.

Binswanger ("Pathologie und Therapie der Neurasthenie," Jena, 1896) writes at length on the influence of pelvic disease in causing neurasthenia. The burden of his introductory remarks is "coincidence." He does not deny that the local lesions may set up the general condition. The pelvis is rich in nerve filaments and plexuses, centrospinal and sympathetic. The prolonged peripheral irritation may excite and then exhaust the nervous centers; and again the failure of general health may complicate the nervous system indirectly. Under this head we may mention chronic endometritis and metritis, malpositions, tumors of the uterus, para- and perimetritis, oophoritis, ovarian tumors, tubal affections. Profuse menorrhagias and leucorrheas should especially be mentioned for their general effects. A local treatment is, of course, indicated, but in the majority of cases this does not cure the neurasthenia. On the contrary, it is not uncommon to see the latter become worse. Hence, even if the pelvic state has been the cause of the neurasthenia, the latter in time becomes an independent condition, uninfluenced by local treatment.

If a woman, not an hereditary neuropath, has a chronic pelvic affection, and some local nervous manifestation occurs secondarily, treatment of the pelvic lesion often produces an astonishing degree of improvement in the consecutive disorder. But when a woman's nervous system is entirely compromised, local treatment is almost impotent to secure improvement, and the neurasthenia may be aggravated. In certain cases the pelvic lesions may be due to that general disturbance which also brings about the neurasthenic state, the latter considerably antedating the former. Again, on account of the great frequency of both the local and general states, very many cases probably represent coincidences. In a few cases arrested development of the genitals may be associated with neuropathic manifestations .

Dercum, the Philadelphia neurologist ("Relation of the Great Neuroses to Pelvic Disease," *American Gynecological and Obstetrical Journal*, 1898, XIII, 119) has the ablest and clearest paper on our subject; he says that when neurasthenia and pelvic disease coexist, it does not imply that there is any necessary causal relationship between the two affections. If a neurasthenic have pelvic disease, the local symptoms are very prominent by reason of the increased reaction of the general organism to local impressions. If neurasthenia coexist with pelvic disturbances, surgical treatment of the latter cannot remedy the former. This is now so well understood that the day has almost expired in which such operations are attempted. The nervous symptoms caused directly by pelvic lesions do not constitute neurasthenia (pain in pelvis, loins, hips, thighs). When pelvic disease and neurasthenia coexist, the latter state is not a contraindication to operation. Nevertheless, neurasthenics bear operation badly, and are extremely prone to nervous shock. Again, surgical intervention in the apparently healthy may be followed by postoperative neurasthenia. To prevent accidents of this character, patients should be treated by baths, massage, rest, forced feeding, etc., before operation. Any idea that operation on the pelvic organs can cure neurasthenia and hysteria, Dercum insists, must be given up entirely. (It is because I see operation urged on these cases still, that renewed protest is in order.)

Loewenfeld of Munich (Sexualleben und Nervenleiden, 1899, pp. 260; very full bibliography) warns against all hasty conclusion that the association of genital disease and nervous diseases implies any causal relation (174). He believes that the protest of the neurologist has brought about important results in checking overzeal on the part of the gynecologist, and draws attention to the Hegar findings among women with symptoms of irritability of the lumbar cord; to wit, that in 15 per cent. the pelvic organs were normal. Loewenfeld admits that the lower the resistance of the nervous system the more intense and widespread the nerve disturbance produced by pelvic disorder—even though that disorder be not great. Even in the case where the pelvic trouble is the sole originating cause of the nervous disturbances, we have to deal with complex relationships, and even when the two are closely tied together a number of other troubles are brought about at the same time greatly obscuring clear judgment as to what influence is to be attributed to the sex-disorder; and all is complicated by a variety of apprehensions—of marriage, of sterility, of pregnancy, of treatment and operation, of cancer, and he adds, by our method of keeping girls and women ignorant of sexual hygiene.

Loewenfeld's conclusion regarding hysteria is, that "we must confess that in the present state of knowledge no trustworthy criteria are available concerning the reflex interdependence of any one of the hysterical symptoms of women and the disorders of the sexual organs" (p. 190). For the worry-neurosis, the most frequent age is between thirty and forty; and hereditary tendency exists in 80 per cent. As causes among women, he found congressus interruptus, and the want of sexual satisfaction from various causes; anesthesia; abstinence, absolute and relative; masturbation; but there is wide variation between individuals in the weight to be given to the sexual harm.

Krönig ("Ueber die Bedeutung der funktionellen Nervenkrankheiten für die Diagnostik und Therapie in der Gynäkologie," Leipzig, 1902) gives an unusually full bibliography of many hundred titles. Of all this number there is no title relating to the connection of pelvic disease and neurasthenia. In contradistinction to the above, there is a copious literature as to the relationship between pelvic disease on the one hand, and insanity and hysteria on the other. Various works on neurasthenia (*e. g.* De Fleury) touch but lightly or not at all on the relationship between this affection and pelvic disease.

Krönig quotes several older authors as to a connection between the neurasthenic state and pelvic conditions. Speaking for himself, however, he is very skeptical. When endometritis is accompanied by profuse hemorrhage the nervous

system must, of course, suffer. However, in most cases of pelvic disorder associated with neurasthenia, there is no causal relation—nothing beyond a mere coincidence. Krönig appears to be an extremist, and his views may be unsafe to follow. He differs from the majority of authors in his views of women. Thus he believes that sexual apathy or frigidity is the rule among civilized women; also that masturbation is a rare vice with the sex. There is a wide divergence between his views and those of specialists on sex, like Havelock Ellis.

Cappelletti ("La Neurasthenie," Milano, 1903) states that the genitals exert a certain influence on the development of neurasthenia, but that this has been exaggerated. In 250 cases of neurasthenia in females, Krafft-Ebing found but nine cases in which affections of the generative organs could be regarded as cause of the nervous condition. Windscheid, in his study of the relationship between gynecology and neurology, attributed but a mediocre influence to the genitals in the production of neurasthenia. However, in treating the latter malady, recovery is favored by treating the local pelvic condition.

The literary reviews in the *Neurologisches Centralblatt*, etc., do not contain much to the point. Special monographic literature on the subject is very scarce.

In presenting a new study of the relation between pelvic disease in women and neurasthenia, I will exclude cases which obscure the inquiry, such as:

1. Patients weak or delicate from childhood.
2. Hysteria.
3. Melancholia, well defined.
4. Mild or transient cases of neurasthenia.
5. Cases with congenitally defective pelvic organs.
6. Cases not fully examined nor long under observation.

The hundred cases are from private practice, selected from nearly three hundred. They are at the opposite end of the social scale from the series studied by Engelhart in Hegar's clinic. They are not merely from the office work of a specialist, as they were partly gathered in the time before I practised gynecology exclusively. Teachers and musicians (14); young women worn out by long attendance on sick relatives; older women, exhausted by rapid childbirth; a few suffering from the shock of accident or operation; college girls, or society women—all are pronounced types of nerve exhaustion of considerable standing. Many are extreme cases. About twenty had come with the office habit fully established, and a few of these in its extreme form. Most of them have been long under treatment. A year of "electricity" within the pelvis, twice a week; weekly "local treatment" for two years; at various stretches for ten years by regular practitioners; biweekly "straightening" of a "telescoped bowel" by our most ignorant and successful quack; and worst of all, innumerable pessaries and tampons holding up normal uteri.

The acquisition of the office habit is not infrequently due to our medical sisters; the general practitioner who does some pelvic work is often at fault; the male gynecologist is far from blameless; and the writer confesses freely that he has been taught most of what he thinks he knows of this subject, by his own lapses from common sense. That obscure and rebellious symptom-complex which we are considering and which we may dread beyond all other ills, presents such a variety of pains and disturbances of function in and about the pelvis in women, that it is little wonder one looks for the causes of hysteria and neurasthenia and melancholia in the sex organs. In these conditions of the nervous system, too, the patient herself, owing to her habits of introspection, emotional excitability, exalted sensitiveness, and self-consciousness, naturally emphasizes this group of disturbances. Her doctor may thus direct his chief inquiry toward her dysmenorrhea, and may persistently treat an insignificant endometritis and sensitive ovary, ignoring mental and physical reconstruction. Thus neurasthenic women readily become sexual hypochondriacs—in the physical sense, not in the moral sense.

A well-balanced therapy would study to keep far in the background this part of the consciousness, for the emotional woman is overbalanced on the sexual side, whether she be conscious of the danger or no. Exalted states of the nervous system are in some inextricable way connected with sex feeling, as for instance during that period in life which develops a religious fervor characterized by its intensity—the period between fourteen and eighteen. This is the period of extreme and unreasoning emotional affection, and it is also the danger-zone for solitary sexual indulgence. There is a secondary time before the menopause that corresponds with the period of most frequent appearance of neurasthenia; but for this earlier crisis one may hardly lay too much stress on sanity and reserve in treatment, and on wisdom and frankness of teaching and training, whether physical or intellectual.

Symptoms Referred to the Pelvis.—I find that *all these women have lumbar pain.* While all complain of sacral distress, at and between the periods, only 46 suffer from "cramps" or pain in the lower abdomen while unwell; 43 complain of irritable bladder; 24 of leucorrhea, and nearly 10 per cent. are *entirely free* from any pelvic distress or disturbance, save backache.

Frequency of Pelvic Disorders.—In 65 the uterus is in normal position. In the remainder, the following abnormalities of that organ are present:

Anteflexion.—In the days when the normal angle in the uterine canal was called anteflexion, and the normal forward tilt onto the empty bladder was classed as anteflexion and a deformity, great bugbears were made of these two. Nor is the practice altogether obsolete. Therefore, a protest against this explanation for the severe dysmenorrhea of the neurasthenic should be again and again placed on record. In our series, if we label "anteflexion" only those cases wherein cervix and body point nearly in the same direction, six cases are found. In five the office habit was strong, yet the results of treatment had been but temporary. Accompanying endometritis was not marked, but accompanying ovaritis was present in five. One case was operated on, an excessive flexion with very pronounced endometritis and scant ovaritis. Incision, and watchfulness after, put an end to all dysmenorrhea and pelvic distress.

Retroversion.—There is one retroversion to every five cases in this series. This is about the usual average among gynecological patients. Among parous women, one in ten exhibited marked retroversion. Of these ten all but one have been anatomical cures, yet failures as far as striking improvement to the general condition goes. Pessary and operation have permanently replaced all but one uterus, and to the pelvic distresses

there has been afforded more or less local relief (as of dysmenorrhea and menorrhagia), but the other symptoms persist. The menstrual upset occurs still. The patients come back asking for pelvic treatment.

Including postpartum retroversion, there are 21 cases. On these 10 operative anatomical cures have been done, either by shortening of the round ligaments or by suspension, but not one *perfect* symptomatic cure accomplished. Partial relief, yes. Glad they had it done, a short time after operation, almost all. Entirely happy they had it done, two years after operation, only 2 out of 10.

Moreover, these are the patients prone to relapse after operation for retroversion. As far as I know, and this was in the time before the post-operative pessary was my rule, my only relapses after suspension or Alexander, have been in patients of this type—patients with great and incurable enteroptoses, patients with the whole weight of the bowels piled onto the uterus. The same is true of kidney fixations in neurasthenics; anatomical cure is easy; *complete* symptomatic cure infrequent.

"It is to be remembered always that it is not, primarily, the amount of displacement, or flexion, that counts; it is the amount of inflammation, hemorrhage, or enlargement produced." These are the criteria as to the stress to be laid on the mechanical defect.

Endometritis.—Very commonly encountered in its milder types, and chiefly affecting the cervix, it is found in 61 of this series. Only five times in 20 operations (and in 1 of these in connection with retroversion) was much material removed from the uterine cavity by the curette. I venture to think, therefore, that the nervous and vascular disturbances of the endometrium are more common than gross changes in the mucous membrane, and that the curette can promise little.

Chronic Ovaritis.—In two-thirds of the individuals on this list (63), I find ovarian abnormalities. Martin quotes 13 to 17 per cent. as a fair average in gynecological office practice. The most frequent condition is chronic ovaritis, chiefly microcystic. Ovarian tenderness of a very pronounced character, and distinct enlargement, and prolapse into the cul-de-sac make up the balance. While the diagnosis of chronic ovaritis is not proven in any case which has not been subjected to ocular demonstration, the findings by bimanual seizure must be approximately correct, as they tally with the exhibits during laparotomy. As many of these patients are thin or have lax abdominal walls, and as many of these ovaries hang low, accurate touch is frequently practicable. Chronic rectal irritations in neurasthenia cause many of the persistent irritations and inflammations of the left ovary. On direct inspection and palpation or resection by laparotomy, the following changes were noted in twenty-two chronic neurasthenics (many of them outside of this series). Ovarian cysts of considerable size were present in 3 cases, ovarian abscess in 1. Chronic microcystic ovaritis was present in 20. Not one abdomen, let it be said, was opened for this condition, in this class of patients.

If you ask, What constitutes a normal ovary, or, Have I ever seen one, or, Is the microcystic ovary a diseased ovary, I answer by this evasion:

For clinical purposes, we may classify the minor variations as abnormal or diseased, should we find alteration in the degree here specified:

The edematous ovary, when the swelling is marked or the knife finds much fluid in the structure; the hyperesthetic ovary, found acutely sensitive at more than one palpation; the varicose ovary, enlarged, with thickened ovarian plexus, seen on opening the abdomen; the dislocated ovary, in the cul-de-sac; the small-cyst ovary, with distinct *tension* of several cysts of a diameter of one-fourth inch or more; the chronically infected ovary, belonging either to adherent salpingo-oophoritis or to chronic proctitis with thickening of the uterosacral or broad ligaments (rare); the sclerotic ovary, in younger women, markedly shrunken as seen by section.

Yet I admit that one and all of these conditions may be present in certain women and the organ functionate without protest.

It would seem plausible, then, if laparotomy demonstrates that the ovaries of these neurasthenics are abnormal, and bimanual palpation can find two-thirds of such ovaries to be in trouble, to reason, from this small series of cases, that the two conditions belong together,—that most chronic neurasthenics have chronic ovaritis. And removal of such ovaries has brought much discredit on surgery.

Fibroids and Arteriosclerosis of the Uterus.—This extensive subject far outreaches my limits. I may only express a belief that there is a large proportion of arteriosclerosis in old cases of neurasthenia; that a single organ may be selected for the vascular changes, and that the uterus is frequently the chosen organ. Alterations in the blood-vessels were extreme in degree in four uteri removed for incoercible and exhausting hemorrhages in women with a long history of nerve exhaustion. (Dickinson, "Intractable Menorrhagias of arteriosclerosis of the uterus," *Brooklyn Medical Journal*, 1906.) After operation the anemia betters, the "monthly tragedy" no longer enacts itself, but the general condition alters little.

With fibroids the usual rule of operating for marked pain, for pressure, for active bleeding, or for complications, must be modified somewhat, under the first indication. As we recall that the neurasthenic pain-gauge has the habit of pointing unduly high, we shall be chary of promise of relief by operation. These be our celiotomy ghosts, that will not down, nor cease to haunt us with so-called "adhesions."

Varicosities of the broad ligament are not easy of determination, except in the most pronounced cases, and such a diagnosis should be verified by laparatomy to be tallied. I believe these to be frequent, but cannot prove it. Indeed, chronic disabling of the pelvic vasomotor apparatus is probably constant. The explanation of the relief given to pelvic aches in certain neurasthenic women by the pessary and the tampon underneath the normally located uterus and ovary, lies in the support of the varicose veins of the broad ligament and ovarian plexus, exactly as the suspensory helps the analogous male varicocele.

The kidneys were subject to a considerable degree of displacement in 19. Of *bladder irritations*, there was complaint in 43, but the systematic study of the bladder in the cases which are troublesome enough to warrant inspection by the cystoscope is too recent to make the report of any value. My observations suggest that the majority of patients presenting an aggravated habit of self-abuse have slight chronic inflammation and varicosity of the base of the bladder.

Rectal Catarrhs.—I have learned that latero-

cession of the uterus, chronic tenderness or thickening of one uterosacral ligament, chronic unilateral ovaritis, and retrocessions of the uterus, anteflexed or not, in the absence of a history of acute pelvic peritonitis, and in the absence of pelvic adhesions and salpingitis, are due to chronic rectal inflammation. Indeed, one may go so far as to predict, in the presence of any right-sided trouble in the above list, that the patient owns a right-sided rectum. As neurasthenics are common subjects of constipation and proctitis, the rectal examination is important and the cause of the pelvic disorder and its therapy are made clearer. Treatment of long-standing rectal catarrh is productive of distinct results, but complete cure is often missed.

Masturbation.—If the following alterations about the vulva are certain signs of solitary sexual indulgence, as I have elsewhere argued at length ("Hypertrophies of the Labia Minora," *American Gynecology*, Sept., 1902), then sixty-five of this series had been, *at some time*, addicted to the habit in a degree sufficient to produce profound changes in the external genitalia. Of these alterations, one or more may be present: labia minora (one or both), greatly enlarged, with cockscomb corrugations; pigmentation, sometimes pronounced; their sebaceous glands often numerous and distended; prepuce usually (alone or in combination), and fourchette (alone or in combination), strikingly duplicated, corrugated or folded, at times pigmented; varicosities about prepuce; dilated meatus, usually with lateral flaps and deep urethral glands; strong levator and anal sphincter. In the ordinary run of 1,000 consecutive cases in gynecological office practice, more than one-third of the patients presented these hypertrophies; of 150 neuropathic women, over half showed them, and in these aggravated neurasthenics, two-thirds, as stated above. At some future time I may have the temerity to try to correlate masturbation and neurasthenia. For the present, let me say that I believe the two matters are coincident, not consequent. It is noteworthy that twenty-one of the women with vulvar hypertrophies are all of the most grievous type of neurosis. On the other hand, four severe nerve exhaustions show no signs. And, moreover, the most extreme and prolonged solitary venereal excesses, in a limited number of individuals, may be shown to bring about no exhaustion of the nervous system.

Endometrium, uterine wall, ovary, bladder base, rectal mucosa,—all suffer from a chronic vascularity, a persistent venous engorgement, and some proven instances of arterial spasm and thickening. These vasomotor changes are alterations, I believe, that belong to the condition, and I hope to see in the discussion light thrown on the question of neurasthenia as a psychosis and where it belongs, and neurasthenia as an arteriosclerosis, and where it belongs—perhaps as a late development, in these worst cases.

Treatment.—The *minor measures*, for relief of pelvic symptoms, are in brief: For dysmenorrhea, bromides with hydrastinin (and helonin); for the menorrhagias, good ergot, stypticin; for rectal mucous catarrh, irrigation with astringents, and cure of constipation; for bladder irritations, water freely, and urotropin.

The *major measures*. After a careful study of the conditions of the patient's life, we plan such remodeling of the habits that each day she spends less nervous energy than she makes, such radical changes in ridding her of special worry or strain as by greatest effort of sacrifice may be possible; such thorough-going training in outdoor life,—first by resting methods, if necessary;—then by development of the muscular system; such a program of forced feeding and long sleeping, and healthful mental attitude and occupation, as to constitute gradual but complete readjustment. These are to be preceded by operation in a very limited number of cases, such as tumors (*e. g.*, ovarian) growing, and necessarily fatal; or exhausting hemorrhages, as from submucous fibroids, or extreme retroversion associated with marked endometritis that will not yield to lesser measures. But with the distinct understanding that the operation is to save life, or to initiate the cure, a first step to the more important measures above, and attended with danger of prolonged nervous disturbance.

Thus, in confirmed neurasthenics with pronounced pelvic symptoms, the hopefulness of the outlook depends not so much upon the operative cure of the few life-endangering conditions as upon the measure of our success in persuading patients to live and work contentedly within the fences of their limitations; on happy mental occupation; on the outdoor habit and outdoor hobby; on graduated muscular training and hydrotherapy; on regulated feeding and resting. What hospitals now are to major surgery, country and suburban sanatoria will become for the education of the sufferers from chronic illness.

APPENDICITIS.

A STUDY OF A SERIES OF ONE HUNDRED AND FORTY-SEVEN APPENDECTOMIES.

By A. E. ISAACS, M.D.,

NEW YORK.

SURGEON, BETH ISRAEL HOSPITAL.

My object in this paper is not to review the subject of appendicitis in general, as its literature is sufficiently voluminous, but to record my personal observations in a series of 147 appendectomies and various deductions drawn therefrom. The series is a consecutive one including all cases in my service at the Beth Israel Hospital within the term of the series that were operated. The few cases that were allowed to recover (?) without operation either by reason of their own refusal or because the indications were not sufficiently definite to demand it, are not included in this report. Otherwise every case was operated, none being refused on account of anticipated unfavorable outcome.

I am indebted to Drs. A. M. Hilkowich, B. E. Sheitlis, and H. Lorber, house surgeons of the hospital, for valuable assistance in the tabulation of the cases.

History of Previous Attacks.—In the records of 140 of the cases, where mention is made of this item, 94 patients denied any previous attack, while 46 admitted from one to five; of these 46, 26 had one previous attack, 9 had two, 4 had from three to five, 5 had continual pains since their first attack, and 2 had frequent general colic for years.

Of these 46 patients with a history of previous attacks the first attack dated back in 2 to one month, in 3 to two months, in 3 to three months, in 6 to between three and six months, in 16 to between six months and one year, in 7 to two years, in 3 to between three and four years, in 1 to seven and in 1 to eleven years. In 4 the time was not recorded.

These figures indicate that 33 per cent. of those coming for operation are recurrent cases, but that does not mean that only 33 per cent. of cases recur. The proportion is much higher and would have to be ascertained from observation of a series of unoperated primary cases. We do not get so many recurrent cases these days because so large a proportion is operated in the first attack; this is shown in this series, in which 67 per cent. were first-attack operations.

While the interval to recurrence may vary from less than a month to more than ten years, the most likely period is from six months to one year. The probability of recurrence is less in proportion to the length of time previous as well as subsequent to that period.

Day of Attack Operated.—Seven patients were operated on within one day of the beginning of the attack, 16 within two days, 22 within three days, 28 within four days, 13 within five days, 11 within six days, 17 within one week, 18 within two weeks, 7 within one month, 1 within two months, and 2 within three months. In 5 the time is not stated.

At first thought it would seem that the delayed cases would prove to be the bad ones, or at least to include most of the bad ones. This would be true if the development of local abscess were taken as the criterion, but it does not apply when general peritonitis is considered as an advanced form of appendicitis. The development of the general infection may occur at any period in the course of a neglected case, but it seems to require peculiar conditions of its own, and is just as likely, as far as we can judge any particular patient, to develop during the first day as later on. Two of the seven patients operated on within the first day of the attack proved to have diffuse peritonitis; 5 of the 16 operated within two days proved likewise; 4 of the 22 in three days, 4 of the 28 in four days, 2 of 13 in five days, 1 of 11 in six days, and 5 of 17 in seven days proved to have diffuse or general peritonitis. Of the 28 dating the beginning of their attacks back more than one week there was but one case of diffuse peritonitis. This patient had been sick more than four weeks and operation showed that he had developed a diffuse peritonitis early in his sickness which had taken the unusual course of localizing itself into multiple abscesses separated from one another by adhesions among the intestines. This was therefore not a late but an early development of a diffuse peritonitis that nature was attempting to cure.

Age and Sex.—The ages of the patients ranged from five to fifty-nine years; 64 were below twenty years of age, and 83 were above. Eighty-nine patients were males and 58 females.

Symptoms.—Under this heading I purpose merely to take up some of the more important symptoms and speak of them as they were exhibited in this series of cases.

First Symptom.—In about 75 of the cases a note was made of the patient's statement as to what was the first symptom he felt when his illness began. Thirty-two, the largest number, gave pain in the right side; 27, the next largest, gave general abdominal colic; 5 mentioned pain in the umbilical region, 3 pain limited to the left side, and 1 pain in the epigastric region; 4 began with vomiting and no pain, and 3 with chills and fever and no pain.

Pain.—Pain, as would be expected, proved to be the most constant symptom. It was prominent in 127 of the cases. In the other 20 it was not much complained of, but could be brought out as an objective symptom. Of the 127 patients complaining of pain, 112 referred it distinctly to the right side, 5 entirely to the left side, 5 to the umbilical region, and 5 to the abdomen in general. Fifty-three of the 112 with pain in the right side began with general abdominal colic which sooner or later became localized to the right iliac region.

Constipation.—The next most frequent symptom noted was constipation, which was present in 103 of the cases. Diarrhea is rather exceptional, yet was present in 6. My rule regarding constipation has always been, even in acute inflammatory cases, to make an attempt to relieve it, generally by calomel followed by enema and salts if necessary, previous to operation, with confidence that the beneficial effect on the patient's general condition of a thorough cleaning out and disinfection of his intestinal canal, and the establishment of intestinal drainage of the peritoneum, by far outweighs the bugbear of fear of peristalsis doing any local damage.

Vomiting.—Vomiting is another of the almost constant symptoms, especially in acute cases. It was present in 100 of this series, including mostly all of the acute and some of the subacute and interval cases.

Dysuria.—This symptom was complained of in 22 cases, and proved almost always to be due to proximity of the inflammatory area to the bladder.

Chills.—Forty-six patients included distinct chills in their histories. Of these 12 had general peritonitis, 19 local abscess, making 31 with pus, and 15 were clean cases. Chills with the onset of the attack are no indication of abscess, but coming on later, especially after four or five days, they are a pretty sure sign of pus outside of the appendix.

Temperature.—The temperature before operation ranged from subnormal to 105.2°. This series indicates that while the temperature is likely to be higher in a case with pus than in a clean case, and still higher in a diffuse peritonitis, no reliance can be placed on temperature by itself in any individual case as an indication of the local condition. The temperatures in the 60 cases without pus were from normal to 103.5°, the average being 100.3°. In the 62 cases with local abscess the range was from normal to 103.6°, and the average 101°. In the 25 cases of diffuse or general peritonitis the temperature was from 96.4° to 105.2°, average 102°. While the temperature is not of much value in the diagnosis or prognosis of clean or local abscess cases, it seems to be of use in the prognosis of general peritonitis, though not an invariable indication even then. In general those presenting the higher temperatures recovered, and those the lower died. Of the 25 cases the temperature in the 15 that recovered ranged from normal to 105.2°. 12 patients having 102° or above, and 3 less than 102°, an average of 101.7°. The 10 that died ranged from subnormal to 102.6°, only 4 having 102° or over, and 6 having less, an average of 100.8°. The explanation of this seeming paradox lies in the fact well known that fever is the natural reaction to the invasion of infection and is an indication of the presence of the good vitality necessary to carry the patient over a severe crisis. On the other hand, absence of temperature indicates a general apathy and want of resistance to the invasion of general infection. Absence of temperature where conditions justify its presence is an unfavorable sign, and its presence, especially when backed by a good pulse, is favorable.

Pulse.—The general unreliability of the pulse by itself as an indication of the local conditions

is well illustrated by the following analysis. The counts here given are those taken on the admission of the patient to the hospital. Besides the local pathological condition other influences, such as the character of the infection, the personal element or idiosyncrasy of the patient, the vital condition as indicated by the variation from normal in the reaction of the system against infection, govern the pulse rate and quality. I have made note of the mortality of the general peritonitis cases under the different pulse rate headings to bring out the point that the pulse in this condition, while not a positive omen, is much more reliable than temperature as such. The pulse was 90 or less in 27 cases of which 16 were clean, 8 had local abscess, and 3 had general peritonitis; of the latter, 2 died. It was between 91 and 100 in 33 cases of which 19 were clean, 11 had local abscess, and 3 had general peritonitis; of the latter, 2 died. It was between 101 and 110 in 24 cases of which 9 were clean, 13 had local abscess, and 2 had general peritonitis; none died. It was between 111 and 120 in 35 cases of which 12 were clean, 15 had local abscess, and 8 had general peritonitis; 1 of the latter died. It was 121 or more in 24 cases of which 5 were clean, 9 had local abscess, and 10 had general peritonitis; of the latter 5 died The pulse normal to the local condition should have a relative correspondence to the temperature, should not be slow with a high or frequent with a low temperature. Either of these discrepancies is a bad prognostic omen. A pulse that retains its usual frequency in spite of an evident local inflammatory condition is not up to the mark and should be looked on with suspicion. Likewise a pulse that has a tendency to run away faster than the provocation justifies is not to be depended on. The pulse has a tendency to run up high in the initial stage of infection, during the stage of lymphangitis before suppuration takes place. Then as it becomes accustomed to the presence of the infection it moderates somewhat. This initial rise accounts for so large a proportion of the clean cases having a comparatively high pulse rate, they having come under observation and been operated during the initial stage. The other clean cases were either chronic in which there was very little sepsis, or they were somewhat older in which the period of invasion had passed or the severity of the infection was already on the decline and the local condition had become temporarily dormant. When a case goes on to suppuration the normal pulse for that condition should be frequent, with morning and evening fluctuations in conformity with the temperature. It may be between 90 and 120. A drop below 90 in the absence of a general peritonitis is not a bad indication, but a rise above 120 is. Taking the severe type of the disease, that where general peritonitis has developed, to illustrate the relation of the pulse to the prognosis it will be noted that of the six cases with pulse below 100 four died, while of the ten with pulse between 100 and 120 but one died, and again of the ten with pulse above 120 five died.

The character of the pulse must also be considered, both in the diagnosis and prognosis. The so-called peritonitic pulse, the pulse of shock, small and wiry, indicates as a rule a diffuse or general infection and in proportion to its smallness and frequency the seriousness of the outlook may be judged. It is not always that the pulse responds in this manner to an extension of the previously localized infection; very often there is no noticeable change at all; but when such a pulse does suddenly appear with concomitant symptoms it indicates the shock of rupture into the general cavity of the contents of a distended appendix or of a local abscess. In the absence of a diffuse infection the pulse is not likely to assume the peritonitic quality, or if it does so temporarily, it does not retain it.

Leucocytosis.—A leucocyte count was made previous to operation in 43 cases, practically the latter part of the series. Twenty-six of these were cases without pus and their average count was 12,900; 18 of these 26 counted below this average, the lowest being 6,000. Of the 8 above the average one counted as high as 30,000, one 22,000, one 21,000, and the other five from 18,000 to 15,000. Eleven proved to be local abscess and counted from 12,000 to 36,000, average 17,500. Six were general peritonitis and averaged 20,700. The lowest was 6,000—this patient died—the next lowest 18,000 and the highest 28,000. These figures go to show that, like pulse and temperature, the leucocyte count in itself is no positive indication of the presence or absence of pus in any individual case, yet it may be of value as confirmatory evidence in the presence of other symptoms. The averages confirm this; 12,700 for the clean cases, 18,300 for local abscess, and 20,700 for the general peritonitis cases. This average for the clean cases is above normal by reason of a few very high counts among them, evidently due to some concurrent condition, while again the average for the general peritonitis cases is low by reason of one very low count, 6,000, surely unusual under the circumstances and indicating an abnormal absence of reaction on the part of the economy owing to which the patient died. There is hope for a more definite indication from blood examination in the differential count of the leucocytes, figuring only the relative number of the polynuclear leucocytes which seem to be the variety proliferated in the presence of abscess.

Choice of Time for Operation.—The question as to the most favorable time for operation has been the subject of a great deal of discussion. My practice has been to operate so soon as the diagnosis has been made, irrespecive of the period of the affection. What may be gained by any other course is more than counterbalanced by the risks of waiting. Interval cases, so far as the local condition is concerned, should certainly be operated as soon as practicable to exclude the possibility of recurrence that may take place at the most unexpected moment. In acute cases in which abscess has not yet developed, my observation has been that the existing inflammatory condition does not add any more to the risks of the operation than if it were done after the subsidence of the acute attack. These cases are invariably closed up after operation and no sepsis occurs. To wait for the subsidence of the acute attack gives us no assurance in any case that it will not go on to suppuration and possibly perforation and general infection of the peritoneum. Local abscess cases are, as a rule, simple and easily handled, yet in some the operation is very difficult on account of extensive adhesions, due to previous attacks, and the risks of working in a septic field are added. Yet my experience has been that the risks even in these severe cases are smaller with immediate operation than with waiting for subsidence. When abscess has formed, and we wait for subsidence, what becomes of the pus? While it may become encapsulated and re-

main dormant for a time this is exceptional and even then it does not remain so indefinitely. If we operate in this stage we have pus to reckon with anyhow. When subsidence takes place after the existence of an abscess, it is because the abscess perforates and discharges, generally into the gut, sometimes into the bladder or other viscera. This outcome is fortunate so far as the immediate danger of the existing attack is concerned, but leaves the patient with additional extensive and dense adhesions of an already crippled appendix to be dealt with in the future operation. Were this course of rupture into the gut assured it might be advisable to wait and have the advantage of working in a clean field, but while waiting for this good fortune the abscess is continually enlarging and involving new areas, and a most unfortunate perforation into the general peritoneal cavity is just as likely to take place as perforation into the gut. In general peritonitis there can be no reason for delay. The patients die if they are not operated, and the sooner the abdomen is opened and drained the better chances have they to recover.

Incision.—The incision used, as a rule, in suppurative cases was the right oblique through all the layers which were again united layer by layer, except for a small opening for the passage of a cigarette drain. In many instances the gridiron incision was found sufficient, but frequently the deep muscles had to be incised above or below the original slit or in both directions to give room for the necessary manipulation. Of late I am using the gridiron incision much more frequently in suppurative cases; if it does not prove sufficient there is always time to enlarge it. In clean cases the gridiron incision was invariably used. In a few the incision was median on account of uncertainty in diagnosis. In one case a second incision was made in the loin and the abdominal one closed because of the peculiar location of the abscess cavity. In the general peritonitis cases where a median incision had been made it was considered sufficient, but where a lateral one had been made the rule was to make a second incision on the left side similar to the one on the right and, after removal of the appendix and necessary attention to the abdominal cavity, to sew them both up again except for the drain openings. This second incision on the left side, while it greatly increases the efficiency of the drainage, takes but a moment to make and does not add appreciably to the time or shock of operation. It is done by inserting two fingers through the right incision and passing them under the abdominal wall to the left side, raising the parieties and cutting right through onto the fingers as a guide. The double incision was made in seventeen of the general peritonitis cases, always with satisfaction to the surgeon and benefit to the patient.

Local Condition.—Sixty were clean cases; that is, had no pus outside of the appendix. Sixty-two patients had local abscess, more or less extensive. Twenty-five had general peritonitis. This gives a series with about 40 per cent. of clean cases and 60 per cent. of abscesses. Of the latter about one in every three was general peritonitis. This is a large proportion of pus cases, and especially of general peritonitis and the reason for it lies in the nature of the service at this particular hospital, which is largely emergency, and which receives most of the urgent cases from the surrounding district in addition to those that come in the ordinary way.

Breaking Protective Adhesions.—The separation of adhesions about the abscess cavity seems to be regarded with general apprehension by the profession on the ground that it would result in the spread of the infection to the general peritoneal cavity. Due to hesitancy in this regard the diseased appendix when not immediately in the operative field is very frequently abandoned to be recovered by subsequent operation or to cause future trouble. It is rather exceptional that the appendix lies entirely within the abscess cavity and can be removed without opening into the uninvolved peritoneal cavity. This may be done when the appendix lies in contact with the parieties anteriorly or laterally, the opposite wall of the abscess being made up of other adherent viscera. In such case the appendix may be peeled up without breaking adhesions that guard the unaffected peritoneum. But generally it lies among and is adherent to the other viscera, making up with them the protective abscess wall. To separate it under these circumstances means to break through the adhesions and expose more or less unaffected peritoneal surface to the septic field. As this latter condition is the usual one very few appendices in pus cases can be excised without opening the general peritoneal cavity. This fear of extension by the breaking of adhesions would certainly apply to intraabdominal abscess that has not been opened for drainage, for here it must result in the extension of the septic process. But the conditions are entirely different in the course of an operation when an outlet is provided for the septic material. Here the drain prevents the accumulation of any surplus, while the peritoneum is able to take care of what little is left. Long ago I lost my fear of breaking these adhesions as I learned from observation of cases in which they were broken inadvertently that no harm was done. In this series three appendices were left on account of the general condition of the patients, but none was abandoned for fear of breaking adhesions, and no case developed general peritonitis or even did badly as a result. Drainage prevents the spread of the infection, and these cases are all drained anyhow, so that this feature adds nothing to complicate the operation. When the exposure of the uninvolved peritoneum has been extensive I use one or two extra slips of gutta-percha tissue from the infected region through the drain opening. Generally even this is not necessary, the usual cigarette drain to the site of the abscess being sufficient.

Location of the Appendix.—In relation to the superficial parts the base of the appendix has a fairly uniform situation at its junction with the lower part of the cecum, to the inner side and posterior. But from this point as a center its body may radiate in various directions, which must naturally influence the locality of the pathological developments when inflammation occurs. The following schedule gives the comparative frequency of radiation in different directions:

Radiating inward toward the median line	14
Radiating inward, the appendix long and anterior to the ileum and its mesentery	6
Radiating inward, the appendix long and posterior to the ileum and its mesentery	9
Radiating downward, below the cecum	40
Radiating downward, the appendix long and extending into the pelvis	21
Radiating upward, anterior to the cecum	6
Radiating upward, to the outer side of the cecum	17

Radiating upward, the appendix long and extending toward liver	6
No record as to location	28
Total	147

The records of the cases herewith given show that the most favorite locality for the appendix is just below and to the inner side of the cecum so that in case of trouble the signs would be most evident at the classical McBurney's point. Radiation in different directions, especially when the appendix is long, gives the variation observed in the location of the pain, etc., in different cases. The longest appendix I have encountered measured 8½ inches, another 7 inches, one 5½, and three 5 inches. No note was taken of those not varying much from usual length, which I should judge to be from 2½ to 3 inches. Especially when the appendix is long and involved near its tip is the location of the signs and symptoms likely to be far removed from the usual position. One of the most troublesome situations is when a long appendix curves up under the ileum and its mesentery in the direction of the umbilicus, and trouble develops at its distal end. Nine such are recorded in this series and they complained of pain on the left side, some presenting no right-side symptoms at all. Two had their abscess cavities wholly to the left of the median line. Diagnosis is always difficult in these cases and sometimes impossible, and is made only after an exploratory, generally median, incision. A long appendix extending downward into the pelvis is a comparatively frequent condition. Inflammation here causes pain from McBurney's point downward, is likely to cause dysuria from contiguity to the bladder, and in the case of abscess frequently causes a condition simulating intestinal obstruction by pressure on the rectum. When the appendix lies to the outer side of the cecum it is in contact with the parieties in that situation, and the region of major pain is just within the margin of Poupart's ligament. When a long appendix in this situation runs upward toward the liver it gives a different picture and is frequently the cause of doubt in diagnosis between appendix and liver conditions. One case in this series was especially marked in this respect. There was a painful mass below the liver with symptoms of abscess. No pain at McBurney's point, no history pointing to or symptoms of appendicitis. Incision was made at the border of the rectus over the mass which was found to be a retroperitoneal abscess to the anterior wall of which the tip of the appendix was adherent. The balance of the long appendix was normal in appearance. The abscess was so unusually situated that it was drained through a lumbar incision, allowing the abdominal one to be closed. The relation of the inflamed appendix to the parietal peritoneum has a marked influence on the severity of the pain. It is well known that the parietal peritoneum is much more freely supplied with nerves and is much more sensitive than the visceral. Consequently when the appendix is in contiguity, as it frequently is, with the anterior abdominal wall or with the pelvic wall, and involves one of these in its inflammation, the pain is much more severe than when it lies among the intestines or below the mesentery.

Condition of the Appendix.—To classify the various conditions in which the appendices were found and be exact is a very difficult matter, as many were the subjects of multiple conditions that would require each of them to be placed under various headings. The following classification takes into consideration only the main pathological feature in each case. It is therefore correct only in so far as that main feature is concerned. Its incorrectness may be illustrated by the fact that most of the perforated and many of the enterolith cases were also gangrenous; many of the perforated and gangrenous cases were due to obstruction of the lumen by enterolith, stricture, etc. The classification was arranged in this manner with a view to illustrate the causative relation of the conditions found to the establishment and course of the inflammatory process.

In 132 of the cases the condition of the appendix was recorded. Of these 40 presented more or less inflammation or the results of previous inflammation mainly evidenced in adhesions. Distension of the organ with purulent contents was caused by the organ being acutely bent on itself, the angulation causing obstruction to the lumen in 7 cases; enterolith was the cause of obstruction to the lumen and distention in 16 cases, and organic stricture in 5. The appendix was gangrenous in 32 instances, and perforated in 32. One of the main causes of trouble in the appendix is interference with the patency of its lumen and consequent stagnation of its contents, which are necessarily septic by infection from the bowel. The simplest cause for such a condition is an angular bend in the continuity of the appendix. This causes retention, local inflammation, and surrounding adhesions which in turn aggravate the condition and close the outlet completely. I have seen in more than one case an acutely bent appendix, its proximal and distal portions adherent to each other, with the distal portion distended and inflamed. On slitting open such an appendix a distinct line of demarkation is observed at the angle, the proximal portion practically normal in appearance and the distal distended with purulent contents and its inner layers gangrenous.

Enteroliths that form by gradual accretion of fecal particles entering from the bowel may likewise be the cause of irritation and adhesions. The inflammatory reaction causes infiltration and thickening of the inner layers that grasp the concretion the more tightly and so close the outlet the more securely, resulting not only in the damming back of the contents, but also in strangulation of the circulation in the distal portion and consequent gangrene and perforation, which latter is very likely to take place from pressure necrosis at the site of the concretion. Another possible result of the presence of a concretion is ulceration of the mucous layer from its irritation and, with the subsidence of the attack and healing of the ulcer, the production of cicatricial stricture of the lumen, partial or complete. Of the five cases of stricture observed three were incomplete. In one just beyond the stricture there was a poppy seed that was too large to pass through, and that acted as a ball valve preventing drainage. The other was an exactly similar condition, but with a small concretion substituted for the poppy seed. In one an incomplete stricture was completed by the swelling of the mucous membrane. Two other cases were complete fibrous strictures without the presence of any concretions and giving no clue as to the cause of the stricture. In both the appendices were found distended with fluid contents but not yet ruptured.

Stricture is probably more frequent than indicated in the above tabulation, as many of the gangrenous and perforated cases might have originated from this cause, the evidence of its

presence having been eliminated in the general destruction of the parts. Likewise angularity and enteroliths must be held responsible for a number of the cases that were found in the terminal condition of gangrene or perforation. My observation has convinced me that most cases are originally due to some such physical cause for obstruction as we have been considering. Yet many are observed in which the appendix is found inflamed, with congestion of the serous coat and infiltration and swelling of the mucous membrane, with no evidence on close inspection of any of the above causes of obstruction. Infection from neighboring septic conditions, such as colitis or infection of the pelvic organs in the female, will account for some of these cases, but most seem to be due simply to the opportunities presented in the stagnated contents of the appendix for the proliferation of the various bacteria that are likely to enter there. Given any cause that interferes with the natural resistance of the parts to the invasion of these bacteria, among which may be included acute gastroenteritis, constipation, rheumatism, the fevers, traumatism, etc., and these bacteria take advantage of the opportunity to proliferate and to enter the tissues and lymphatic circulation and thus start the process that if not checked results eventually in lymphangitis, gangrene, perforation, and abscess.

Mode of Amputation.—Much has been written regarding choice of the mode of amputation of the appendix and various methods have been advocated. I have limited my work to a few of the methods, and make my choice not by routine preference for one or the other, but by the conditions in each individual case that make one or the other more suitable.

Ligation of the stump and cauterization of the exposed mucosa was done in fifty-eight of the cases. Separation of a peritoneal cuff and stitching the same over the ligated mucosa and muscularis was done in 16 cases; inversion of the stump, with purse string suture, 52 cases; decapsulation of the appendix, with either ligation or inversion of the core, 14 cases; the appendix found spontaneously amputated, 4 cases; not excised, 3 cases. Of the three appendices not excised one was in a case of extensive suppuration in very bad general condition, another in a case of general peritonitis, also in extremis, and the third was the only one in the whole series in which the appendix could not be located within the amount of time and manipulation thought justifiable at the time for the sake of its recovery. This patient passed out of my hands, but I am informed that he had two recurrences and two subsequent operations, the appendix being secured at the third operation, subsequent to which he remained well.

The method of ligation and cauterization of the stump with the actual cautery or with carbolic acid, followed by alcohol, and the return of the stump in this condition to the abdominal cavity, was the one I previously used, and from a practical point of view, judging by results, I have no fault to find with it. It has never caused any trouble, either in closed or drained cases, except once, in a case operated previous to this series, and there the cause was that the cecal attachment was unusually situated on the front of the cecum, allowing the stump to point directly into the drainage opening. It became adherent there and its orifice subsequently became patent and formed a fecal fistula. This was a very interesting case in other respects also, and was fully reported in the Medical Record, April 18, 1903. While this simple ligation method may be practically good it is not theoretically nor anatomically correct, for various reasons. One is that the sterilization of the stump by cauterization cannot be entirely depended on. Another is that the ligature brings in apposition mucous surface to mucous surface, which cannot unite except when the mucous layers have been destroyed by disease. The closure must take place by union of the raw edges of the stump where amputated, or where ligated, if the ligature be tight enough to strangulate the distal portion, with the serous covering of the adjacent viscera, thus necessarily causing adhesions. In the case mentioned there were no adjacent viscera and when the ligature either gave way or cut through, no union taking place between the apposed mucous surfaces, the appendical orifice remained open. This method is useful, in fact is about the only practical one, in the condition quite frequently encountered where, by reason of the proximity of the abscess to the base of the appendix, the latter is infiltrated and inflamed and too brittle to hold sutures or stand inversion or manipulation. In other cases this method, taking less time than any other, is applicable where time is a consideration, especially in general peritonitis. In pus cases that must be drained, there is no use wasting time on sterilization with carbolic acid and alcohol, or with the cautery as the condition of the stump is no worse than that of its surroundings.

The method of peeling off a peritoneal cuff from the appendix extending for about a half inch from its base, ligation of the core within and stitching the cuff over the stump, was used early in the series. It is an improvement on the plain ligation method, as it provides a covering for the end of the stump thereby avoiding adhesions. Yet it is open to the theoretical objection that beyond the ligature there is left a portion of secreting mucous membrane if the ligature has not strangulated it, or a nodule of necrotic tissue if it has. In the former case it leaves a portion of the appendix unexcised, which may either drain its normal secretion into the cecum if the ligature has not caused an obliteration of its lumen, or if the lumen has been closed by the ligature may, by its own secretion, become the nidus of a septic or cystic sac. These objections are theoretical only. I have not had any unfavorable experience with it, but have discarded it for the method I use at present.

What I consider the ideal method in all cases where it is applicable, is inversion of the stump and a double suture to close the orifice and to cover in the raw edges and stump of the divided mesoappendix. What is left of the secreting surface of the appendix is inverted without any ligature into the cecum where it can never do any harm, and all the raw surfaces made during the operation are covered. The technique is carried out as follows: The mesentery is ligated, the ends of the ligature being left long for future use, and divided to the cecal junction. There will be seen two-minute bleeding arteries after this cut near the base of the appendix, which are easily controlled by temporary clamp or by twisting. The assistant now holds the appendix up vertically, with a blunt clamp which will not break it, while a purse-string suture of fine catgut is inserted in the serous and muscular layers of the cecum around and well outside the base of the appendix, beginning at the incision in its

mesentery, going all around, and ending at the same point. The stitch half way around opposite the mesentery is not drawn taut, but is allowed to form a free loop which is temporarily held in the eye of an artery clamp. The free ends on one side and the loop on the other serve as tractors by which the assistant raises the cecum at the base of the appendix, spreading the threads on either side so as to open out its lumen. A strip of gauze is laid around the base of the appendix under this tractor to protect the gut from any possible drip of fecal matter when the appendix is cut through which is now done proximal to a clamp placed about a third of an inch from the cecal attachment. With the assistant still holding up the tractor and spreading the cecal orifice by holding the threads apart, the end of the stump is caught with a small pointed clamp and easily inverted. While held in this position for a moment the assistant makes a tie in the free ends of the ligature and draws it taut, taking up the loop and tightening the purse string around the clamp which holds the inverted stump in place. The clamp is now loosened a bit, so as not to draw the stump out again with it, and removed, the suture is tied and the ends are left long. The instruments used in the section of the appendix are put away with the specimen, the gauze strip around the stump is carefully removed, and the parts are wiped with a wet sponge. The long ends of the mesenteric ligature and the purse-string suture are now used as tractors to raise up that portion of the cecum to be sutured. The purpose of this final suture is to cover in the raw edges of the mesentery and its stump and to reinforce the purse-string closure of the appendical orifice. A Czerny stitch is taken to one side of the base of the mesenteric stump, then inserted into the top of the stump proximal to the ligature, and again into the cecal wall on the opposite side. When this stitch is tied it buries the stump within the inverted cecal wall. The suture is continued as a running Czerny towards and well over the appendical orifice, taking in sufficient of the cecal wall on either side to cover it securely. This gives plenty of apposed serous surface for the desired union, leaves a smooth rounded cecum with no stump, and leaves no raw surfaces to form adhesions. This method is not new, but the one feature that, as far as I know is original with me, is the burying of the mesenteric stump by the suture that reinforces the purse string closure of the orifice.

All clean cases and the majority of suppurative ones may be handled in this way. But when the base of the appendix is involved and too infiltrated and brittle to hold the stitches, the method can not be used. The element of time may enter as a consideration in other cases. It does not take as long to do as to describe, yet it takes a little longer than the plain ligature, and where this little time is not of vital importance the ideal results more than compensate for it.

Decapsulation was done in fourteen cases. This procedure does not refer exactly to the treatment of the appendical orifice, but to the enucleation of the body of the appendix when it is bound down and involved in adhesions. Such cases are frequently encountered and it requires considerable time and patience to separate these adhesions. In doing this the gut may be injured or troublesome hemorrhage produced, either or both of which may prolong the operation more than the condition of the patient might justify. A simple method of overcoming these difficulties is to split the peritoneal coat of the appendix in any portion of its length available, separate it from the core composed of its inner layers, and follow up this core in either direction until the whole organ or that part involved in the adhesions is freed. Then the core, the only offending portion, is removed and the adherent capsule is allowed to remain *in situ*. When the appendix is removed in this way there is no necessity for the preliminary ligation of its mesentery, and if the incision in the peritoneal capsule is made opposite the mesenteric attachment there is no bleeding requiring attention. The closure of the appendical orifice may be by any one of the above mentioned methods which is most suitable to the conditions of the particular case. This method of decapsulation I have fully described with illustrative cases in the MEDICAL RECORD, April 15, 1905.

Four instances were encountered of spontaneous amputation of the appendix; that is, the appendix was found entirely separated from the cecum by its own destructive inflammation, and the cecal orifice closed. This might occur as the result of a concretion impacted near the cecal orifice, causing pressure necrosis and separation of the appendix, the orifice closing as a result of the active local inflammation. Stricture at or near the orifice of the appendix is found occasionally to be the cause of distention and inflammation of the appendix, and such a condition could also likely result in gangrene and spontaneous amputation with closure of the appendical orifice.

Drainage.—The manner in which drainage is used is a most important consideration in every case in which pus is encountered. It is here an indispensable measure, but should be used properly. Overdoing it may result in complicating the case and causing protracted convalescence. Not using it where indicated is likely to result in no convalescence at all. Where no pus is encountered the accepted procedure is to close the wound entirely. There are a few operators who are brave enough to close in some instances after having cleaned out the pus, trusting to the absorptive powers of the peritoneum to take care of what is left, or hoping if that fails that the resulting suppuration will find the line of least resistance along the course of the incision and so work its way to the outside world. This would probably be the result in the majority of the cases thus treated, but in a minority it would work the patient along to the next world. There is no justification for taking these chances, for just as good and quick results can be had with the insertion of a small rubber tissue drain between the stitches to be removed in twenty-four to forty-eight hours, which will not interfere with primary union in those cases in which absorption takes place and will give an outlet for the infective material in those in which the infection persists.

The abuse of drainage is in overdoing it. The old method of packing any amount of gauze into the belly is now obsolete, but as a rule too much drainage is yet used. The object to be attained in drainage of the abdominal cavity is to give sufficient outlet for any possible exudate, and at the same time to repair the abdominal wall, for the prevention of hernia, as perfectly as is consistent with the presence of efficient drains through it. It must be remembered that the abdomen is not a cavity with rigid walls, and that it is filled with more or less flaccid and movable viscera; that the walls and contents adapt themselves to

each other so that the cavity is always practically filled, leaving no dead spaces. When an abscess forms among the viscera and its contents are removed by operation the natural tendency is for its walls to collapse, the viscera occupying the space previously taken up by the abscess. This process is sometimes retarded by the rigidity and adhesions of the walls of an old abscess, but even here as the infiltration subsides after removal of the cause the walls very soon collapse and obliterate the cavity. All the drainage that is required in these circumstances is an outlet for the passage of the amount of new exudate thrown out, and sufficient for that purpose is a small "cigarette drain" or even a narrow slip of gutta-percha tissue from the site of the abscess out through the abdominal wall. There is no sense in packing a large or even small amount of gauze into the cavity, for that only prevents its collapse, affords a reservoir for the stagnation of pus, and by the irritation of its presence causes the continuation of the surrounding infiltration and aggravates the adhesions. On the other hand the presence of the small drain allows of the collapse of the cavity, leaves no space for the accumulation of pus, which is forced out as it is formed, and allows of speedy obliteration of the cavity by gradual union of its apposed walls.

The drain used in abscess cases consists of a strip of gutta-percha tissue folded into four to eight layers, an eighth to a half-inch wide. When more seems to be needed a "cigarette drain," a strip of gauze rolled loosely in gutta-percha tissue making a cigarette of about the diameter of a lead pencil or a little larger, is used. This passes from the abscess cavity, or from the deeper parts if adhesions have been broken, exposing uninfected peritoneum, out through the wound. The latter is closed up layer by layer, leaving a little extra space between the two stitches where the drain passes or omitting one stitch for it. Gauze should not be used directly in contact with the peritoneal surface except where necessary for the control of hemorrhage. It becomes adherent to the surface and draws the intestine out of place with it in its removal besides leaving a raw surface likely to form adhesions.

Fowler's position is always advantageous even in local abscess, for besides the reason that he gives for it in general peritonitis, gravitation of the exudate to the pelvis where it is less likely to be absorbed by the lymphatics, gravitation also forces the viscera into the pelvis and lower abdomen and helps thereby to close the cavity and force its contents out of the belly.

The drainage in subsequent dressings depends on the behavior of the case. It is removed in twenty-four to forty-eight hours, not to be replaced at all in some cases. Generally, though, where there has been considerable pus at the operation, it is safer to replace it, and especially where pus is found at the dressing should it be continued. A similar drain is used, but inserted not quite so deeply. Subsequent dressings are at intervals of one to two days, and the drain is made shorter each time the conditions justify. It is very exceptional when a larger drain has to be inserted. The less drainage used consistent with the requirements, the less the suppuration and the shorter the convalescence.

Mortality.—In the 147 cases there were 15 deaths. To apply this mortality rate to prognosis in general would be incorrect, as the mortality of clean cases, which should be nil, or even of local abscess cases, which should be low, is very different from that of general peritonitis cases which must be comparatively high. Another important element in prognosis are the pre-operative complications, which if present may prove the cause of death in spite of favorable progress of the local condition. Postoperative complications, naturally, cannot be reckoned with before operation, but the possibility of their occurrence must be kept in mind. Of the 60 clean cases one patient died. This was his second attack of appendicitis and he had, in addition, a severe influenza on account of which operation was delayed for some days. He developed a postoperative general peritonitis, cause unknown. The lowered vitality brought on by the influenza no doubt contributed toward the fatal end.

Of the 62 local abscess cases 4 patients died. One was a five-year old child with a bad pulse. very large abscess, and very septic, on which the operation seemed to have no effect, the sepsis progressing till death took place. The second had a pre-operative severe bronchitis, cyanosis, and bad pulse, and developed a postoperative pneumonia which took him off on the fourth day. The third was doing nicely for three weeks and almost well, when for some unknown reason he developed a general peritonitis and died. The fourth was a septic case with extensive abscess. He did well for six weeks, when he developed signs of abscess of the liver. Secondary operation, rib resection, and exploration of liver, was done but without benefit.

Of the 25 general peritonitis cases 10 patients died. In 8 of these death was due practically to a continuation of the general sepsis. Another one did well for more than a week, when abscess of the liver developed with pronounced jaundice. The tenth should hardly be put in this class as his peritonitis had passed the acute stage and gone into a condition of multiple circumscribed abscesses from which about two quarts of pus were evacuated. His death could not be charged directly to this condition, from which he might have recovered. had it not been for a secondary operation for fecal fistula. The fistula was due to injury of the gut in separating the dense adhesions between the intestines to afford an outlet to the abscesses among them.

240 East Broadway.

FILTRATION OF PUBLIC WATER SUPPLIES.*

By CASSIUS E. GILLETTE,

MAJOR OF ENGINEERS, U. S. ARMY.

The water supplies of cities are generally drawn from streams or lakes, both of which are always liable to contamination with disease-producing germs, especially of typhoid fever. Many supplies are drawn from rivers almost certain to be infected from the sewage of cities above, and many cities pump their own diluted sewage into their water reservoirs. Often large sums are spent to get a water supply from mountainous or sparsely settled regions, but immunity from typhoid is not thereby obtained. It is a noticeable fact that mountain districts, where only sparkling streams prevail, are often scourged with epidemics of typhoid. Maps accompanying the report of the census of 1890 indicate rather more typhoid in the country along clear streams in the Appalachian region than along the muddy streams of the Atlantic Coast plain, or the Mississippi Valley. This is probably partly due to

*Read at a meeting of the Medical Association of the Greater City of New York, February 12, 1906.

the fact that if a clear and pure stream happens to get contaminated the germs live much longer than they do in muddy streams or waters teeming with other bacteria. Hence, even a mountain water is unsafe as a supply unless the whole region is rigorously policed, which is practically impossible. Such a supply may be safe for many years and yet ultimately cause an epidemic. One typhoid case anywhere within the watershed may pollute the entire supply.

It would, therefore, appear that no source, subject to inflow surface water, is safe unless measures be taken to remove the dangerous bacteria before the water is used. Three methods of making such a removal exist in nature:

(1) Quiescence for a long time to permit the germs to die or settle to the bottom.

(2) Flow for long distances in streams bearing sand or silt. Such streams are constantly depositing their burden and eroding new material. This deposition seems to carry with it the bacteria and most of the decomposable matter. The Missouri river water, for example, after the mud and sand are settled, has remarkable keeping qualities, and is a good drinking water, except where taken near and below a city.

(3) The process of soaking into the ground, reappearing as springs or artesian wells which are usually of good water. However, springs in thickly settled, rocky regions are not certain to be safe. Shallow wells in towns or cities are extremely dangerous.

Artificial means of purifying large surface water supplies have generally been made in imitation of the first and the third of the above natural processes. Large reservoirs settle out both the mud and the bacteria. They are open to the objection that under certain conditions they develop growths that are disagreeable, if not injurious; that the accumulations in the bottom become very foul, and that their construction of a sufficient size is expensive and often impracticable.

Slow sand filtration doubtless started as an imitation of nature's way of purifying by soaking through the earth, although the process is really not exactly the same. This system is undoubtedly the most practicable and reliable method yet devised for general use with large water supplies. Its strong point is its certainty. Ignorance or negligence may lessen the output, but only wilful mismanagement will produce a dangerous product.

With certain muddy waters, however, the expense of operation becomes very great. In these cases many cities have adopted a system of mechanical filtration in which the mud is first coagulated by alum, or some equivalent, and then strained out with the bacteria by forcing the water rapidly through a coarse sand strainer, which is cleaned at intervals by mechanical means. This system requires careful and intelligent management, for the proper quantity of alum varies with the condition of the water, and a variable quantity of lime has also sometimes to be added to the water to produce good results. A more serious trouble results from the failure to add enough alum. Carlessness in this respect may permit the dangerous bacteria to go through the filter with little or no improvement in the water.

There is a widespread prejudice against the use of alum, based on the idea of its presence as such in the filtered water being injurious to health. There appears, however, to be no foundation for this. Careful management of mechanical filters will give good water. The danger lies in inattention.

Slow sand filtration consists in causing the water to sink slowly through a bed of clean sand, from one to three feet thick. Originally devised as a simple, natural strainer, it has been discovered that the action is more complicated and effective than mere straining. In the operation of a filter in the early stages the results are generally poor until the sediment and bacteria in the water, settling on the surface of the sand, have partly clogged the interstices and formed a thin gelatinous layer over the particles of sand forming the surface of the filter. This "schmutzdecke," as the Germans call it, undoubtedly constitutes the most essential part of the system. Its exact action is somewhat obscure in the present state of the art. It probably acts in some or all of the following ways:

(1) The coating of each particle of surface sand makes a finer strainer by diminishing the interstices. In this it is doubtless assisted by the deposited fine silt.

(2) After the film is once formed the other bacteria are caught by adhesion.

(3) The colony of bacteria on the surface may remove from the water part of the food supply or oxygen, or other substance necessary to the existence of those bacteria that pass into the sand below, and they die of starvation or for the lack of something necessary to their existence. The removal of oxygen in the filter is sometimes quite marked.

(4) The bacteria of the gelatinous layer may give off some substance that is toxic to those which pass into the depths of the sand and aid in their destruction. The writer has recently had a test made in one of the Philadelphia filters that indicates an increase in the carbonic acid content of the water. This may help cause the destruction of those bacteria that get through the surface or at least help prevent their multiplication in the sand or underdrains.

If such increase in carbonic acid should prove to be a general accompaniment of sand filters to any material extent, it may throw some light on several things, as for instance, the possible increase in hardness by the increased solution of lime from calcareous particles in the sand or the gravel. It is a generally observed fact that algæ grow more freely in water after it has been filtered than before. The increased carbonic acid may favor this vegetable growth. In this event it might be cheaper to lessen the carbonic acid by some simple process than to build expensive concrete covers for the filtered water reservoirs. The subject is worth investigating.

The above four methods seem to cover all the ways in which the filter can act, and they all probably contribute to the result.

That simple straining is an important part is indicated by the fact that in the Maignen system a quickly prepared slow sand filter is produced by adding to the fresh sand surface an artificial "schmutzdecke," composed of comminuted asbestos.

The filters in Washington are composed of very fine sand and the water is considerably purified by sedinemtation. No recognizable "schmutzdecke" is formed.

That the layer of bacteria is generally essential is shown by the fact that a second sand filtration of water does not improve it, but on the contrary generally adds to its bacterial content.

As the quickness with which the "schmutzdecke" is formed and its efficiency must depend somewhat upon the bacterial content of the applied water, it would seem unnecessary, or even inadvisable, for a city to go to the tremendous expense of bringing in a mountain supply to be filtered, if a reasonably

good supply could be obtained at a nearer point. The bacteria in the nearer supply, while they would injure it for direct use, would be harmless, or even advantageous, in a supply to be filtered.

This principle, however, should be applied with some limitations. It is not advisable for a city to filter water that is positively dangerous, as, for instance, to use a supply contaminated by its own sewage, but an ordinary river water, taken from a point not immediately below a large city, is generally plenty good enough for filtration and may be much more economical than a mountain supply, both from less first cost and better adaptation for filtering purposes.

Thus, in the writer's judgment, it requires other reasons than mere improvement in quality for the City of New York to go to the distant mountains for water to be filtered if a reasonably good supply can be obtained at less cost from the Hudson, at the point where the proposed conduit line crosses that stream. On the other hand, the present plans for Philadelphia contemplate filtering water from the Delaware, subject to present and ever-increasing contamination from the city's own sewage. This may be tolerated at present, but nothing should be done to prevent a future supply of reasonable good quality from above Trenton.

In the operation of slow sand filters, the filtration part itself is a comparatively simple matter, while the civil engineering of designing plants for economical operation is a quite complicated subject. Costs of land, of construction, of pumping to different elevations, of cleaning filters, sand renewals, etc., render any particular case a matter for most careful consideration and scientific treatment.

The cost of cleaning and operating is perhaps the most important element, to which not enough rigid investigation has yet been applied. After a filter has been in use a few days it is necessary to increase the pressure to force the water through the filter at the proper maximum rate. This is done by increasing the difference in level or head between the applied and effluent waters. This is generally called "loss of head." On account of necessary construction it is impracticable to increase this loss of head beyond a certain amount. When this is exhausted the filter must be put out of commission and the surface scraped off. The frequency of these scrapings, on which the cost of operation principally depends, is rapidly increased by unfavorable conditions of the applied water as to turbidity, bacterial content, or other qualities.

Two principal methods have been used to prepare the water for effective filtration, with a view to prolonging such period of operation, or "run," and of adding to the permissible daily rate, thereby increasing the output. These methods are sedimentation and preliminary filtration, or "scrubbing."

If water is kept quiescent in a reservoir for a few days it will, during unfavorable periods, improve the quality, so that with equally good results the runs of the filters may be materially lengthened and the rate increased. Similarly, various rough, rapid filters have been used to prepare the water.

Which is the best plan is, in the present state of knowledge, a matter of experiment for any particular water, and its determination greatly adds to the complexities of engineering design.

The writer has attempted to deduce, from the records in the Filtration Bureau in Philadelphia, what constitutes the best preliminary treatment of Schuylkill river water at that point; to determine by the records of the slow sand filters what conditions of the applied water have given the greatest runs and at the same time have been accompanied by good results.

There are three separate filter plants that have been treating this water for many months: Upper Roxboro, where the water is settled for about two weeks; Lower Roxboro, where it has a slight sedimentation and is treated by preliminary filters consisting of an upward flow through coke and a top layer of sponge clippings, and Belmont, cohere the water is used after a little sedimentation. Daily observations have been continuously recorded at each filter, showing turbidity and bacterial content for both applied and effluent waters, loss of head, and other elements of the problem.

Obviously the preparatory treatment should be directed to the production of such a water as will give a good effluent from the sand filter and at the same time produce the minimum increase in the daily loss of head, thereby prolonging the "run." It has generally been considered that such daily loss of head is caused entirely by the clogging of the sand filters with mud, aided perhaps by the bacterial jelly, and that the preliminary treatment should be directed simply to reduction of turbidity.

While the results obtained by following this idea have been fairly satisfactory, an analysis of the operation of the three plants above mentioned do not indicate any very striking connection between turbidity or bacterial content and loss of head.

Thus, take the run of a filter bed at Upper Roxboro from February 19 to May 13, 1905, a long run of 85 days (but at only about one-third the normal rate of three million gallons per acre per day). During the first thirty days the water was very clear; during the next thirty days quite muddy. The daily loss of head was about the same during the two periods. During the last twenty-five days the water cleared up considerably, but the daily loss of head was very much greater than during the earlier part of the run. During the first third and last third of the run the bacteria was low; during the middle third very high. Apparently after this filter had taken care of a certain quantity of mud it rapidly went out of commission, irrespective of what kind of water it received thereafter. At the same place the loss of head, during the summer of 1904 and during the spring of 1905, was less for high turbidities than for low. On the other hand, when the bacterial content was over 35,000 per cubic centimeter, the filters clogged much more rapidly than when under that figure. At this place, after two weeks' sedimentation, the turbidity and bacterial content are rather independent of each other. In general though, at these filters the clogging is more rapid with high turbidities than with low, but, as stated above, there are some rather remarkable exceptions to this.

At Belmont, taking the entire run of the filters since they were started, we find that on the average the loss of head caused by twenty-seven observations of a turbidity of 160 (silica standard) is actually less than the average caused by a turbidity of only 5. The average loss of head corresponding to waters of over 150 turbidity is not 50 per cent. greater than that caused by turbidities of less than 10.

The loss of head at this place was apparently little influenced by the numbers of bacteria present. At this place even the short sedimentation period seems to make the amount of turbidity and the bacterial content more independent of each other than in the raw river water.

In the river, while as a general proposition the numbers of bacteria are greater when the river is muddy, the two do not go hand in hand. Gener-

ally an increase in the turbidity, following a prolonged low stage, is accompanied by a marked rise in bacteria. This may fairly be attributed to the washing in of accumulated bacteria on shore and from small streams. The following floods are naturally less contaminated. The latter part, too, of a prolonged flood is not so contaminated as the first part, because the first washings have gone and the settling of part of the mud has carried down the bacteria and purified the water. In the winter, on the other hand, the bacteria will often rapidly increase while the water remains clear. This is probably due to a variety of causes. It is well known that bacteria rapidly increase in reservoirs in winter from multiplication. In the river this doubtless takes place also to some extent. Light rains or thawing snow may wash in abundant bacteria, with no disturbance of the frozen ground.

At Lower Roxboro, where the water is given a rough preliminary filtration, the water applied to the sand filters shows a closer relation between turbidity and bacteria than does the raw river water, and the daily loss of head seems to increase directly with each.

Comparing the advantages of preliminary filtration at Lower Roxboro with the two weeks' sedimentation at Upper Roxboro, the average daily loss of head is about double where the preliminary filters are used. But, as the rate at the latter place is about double the former, honors seem to be about even with the two methods. Preliminary filtration seems to give rather the better results in summer and sedimentation in the spring. In the fall and winter the difference is not marked.

The various elements of the problem for the Schuylkill water have been tabulated and plotted on a large variety of assumptions, but thus far about all that can be said is that in general the removal of the mud improves the water for filtration, partly by lessening the sediment, partly by removing excess of bacteria, or of certain classes of bacteria, and perhaps partly by the incidental improvement of the water in some other respect not yet determined.

The indications also are that the most economical preparatory treatment of this water is, for part of the year, by sedimentation, part of the year by both sedimentation and preliminary filtration, and occasionally to use the raw water direct.

It will be seen that where preliminary treatment is necessary, as it generally is, the subject of filtration becomes much more complex, especially as to the economics of engineering design. In the present state of knowledge experiment alone will show the best system for any particular case. As such experiments take time, it would be the part of wisdom for every municipality, drawing its supply from streams or lakes, to inaugurate small testing plants to determine the best way of purifying its water supply, even if such purification on a large scale is not contemplated in the immediate future.

PUBLIC WATER FILTRATION IN MASSACHUSETTS.*

BY CHARLES HARRINGTON, M.D.,
BOSTON,
SECRETARY OF THE STATE BOARD OF HEALTH OF MASSACHUSETTS.

THE fact that the State Board of Health of Massachusetts has for many years conducted, and is still carrying on, extensive and important investigations in the field of purification of water and sewage, at the Lawrence Experiment Station, and that it has the general oversight of all but certain specified inland waters of the State and acts as an advisory body in all matters of public water supply and sewage disposal for all the cities and towns, has given rise to a somewhat prevalent idea that Massachusetts, as a whole, is largely supplied with filtered water. This impression is, however, decidedly erroneous, for within the Commonwealth there are but five communities which filter their water, and but one of these, Lawrence, is a place of any considerable size. The public water supplies of the State are, in general, very efficiently guarded against pollution at their sources, and hence, with few exceptions, are not in need of purification before distribution. Of the five supplies that are filtered, but one is so treated because of danger in the use of untreated water.

The town of Athol employs a "mechanical" filter, with alum as a coagulant, because its water supply contains an abundance of Anabaena, from which arise disagreeable taste and odors. The town of Reading uses the same kind of apparatus on account of an excessive amount of iron. The towns of Milford and Hopedale have a supply in common: partly surface water, which has decided color, and, according to the amount of overgrowth of Anabaena and other organisms, disagreeable taste and odors; and partly ground water. For the reduction of color, odors, and taste, this supply is subjected to filtration through a sand filter-bed. In none of these towns has there ever been any large amount of typhoid fever, and, in consequence, a comparison of the death rates from this disease, before and after the installation of the filters, yields no results. In Hopedale, for example, the total deaths from typhoid fever, in the twenty years ending in 1904, were but 8 in number; in Milford the number was 58; in Athol, 31; in Reading, 16.

In the case of Lawrence, which is a manufacturing city, having at present a population of 69,939 (census of 1905), the conditions are different. Lawrence is situated nine miles below the city of Lowell, on the Merrimack river, into which the latter city discharges its sewage, and from which the former draws its drinking water, about a fifth of a mile upstream. The high death rate from typhoid fever in Lowell and Lawrence, in comparison with that of other cities of Massachusetts, was investigated in 1890 by the State Board of Health, and it was demonstrated that the large incidence of the disease in Lowell was due to infection of the river by cities and towns above, and that the greater incidence in Lawrence was due to the further infection of the river by the sewage of Lowell; whereupon the board, which, shortly after its reorganization in 1886, had established an experiment station at Lawrence for the study of purification of water and sewage, took up the problem of a system of filtration which would remove all pathogenic organisms and supply an adequate supply of purified water to meet the demands of the city. The result of the work was an experimental sand filter which produced practical sterility, filtering at the rate of two millions of gallons per acre daily; and, in 1891, the city was advised to install such a filter of proper size to meet its needs. In the following year the city government undertook the construction of the filter under the direction of the board. Without going into the details of construction, let it suffice to say that in September, 1893, a gravity sand filter-bed of two and one-half acres was completed at an expense of about $65,000, capable of furnishing five million gallons of water per day. The chemical changes in the water were noted from the beginning of the application of the river water to

*Read at a meeting of the Medical Association of the Greater City of New York, February 12, 1906.

the filter, and were very marked. The diminution in the number of bacteria in the effluent was also observed from day to day. In the first three days this amounted to but 25 per cent.; in the next three days it was 70 per cent.; and after three weeks it amounted to 98 per cent.; and then, as time went on, it went to 99.3 per cent. Eight months after its use was begun, the effluent contained but 1.7 per cent. of the original number of bacteria in the applied water, and the number was still further reduced during passage through the mains and service pipes, so that the water as delivered at the tap in the City Hall contained less than 1 per cent. of the original number.

The results of the change in the character of the water on the health of Lawrence have been very striking. In the first eight months, the typhoid mortality dropped 60 per cent., and of the 40 per cent. of the former mortality, nearly half was due to the use of unfiltered water taken by mill operatives directly from the canals, in spite of posted warnings at all faucets in the mills in which such water could be drawn for washing purposes.

Prior to the installation and use of the filter the typhoid death rates per 10,000 population were as follows: 1890, 13.44; 1891, 11.94; 1892, 10.52. The filter was completed in September, 1893, and was immediately placed in service. The rate for that year was 7.96, and subsequently as follows: 1894, 4.94; 1895, 3.45; 1896, 2.59; 1897, 2.50; 1898, 2.41; 1899, 3.48 (the increase due to imperfect working); 1900, 2.08; 1901, 2.03; 1902, 2.29; 1903, 3.44 (the increase due, in part at least, to infected milk); 1904, 1.61.

As an instance of the protection afforded by filtration may be cited the fact that, in spite of the occurrence of an outbreak of typhoid fever in Lowell, between August and December, 1903, in the course of which no fewer than 231 cases were reported, and, notwithstanding the amount of infective material which must have been poured into the river in the sewage of that city, not a single case of the disease occurred in Lawrence which could be traced to the use of the filtered river water.

Illustrative of the bacterial efficiency of the filter may be cited the following figures:

Monthly bacterial counts of the river water at the intake during 1900 showed from 3,200 bacteria per cubic centimeter (May) to 19,200 (September). The effluent showed less than 100 bacteria in every month but January (110) and as low as 17 and 18 (August and September). The highest number in the water at the tap in City Hall was 83 (January), and the lowest was 12 (August).

In 1901, the number in the river water ranged from 1,300 to 8,900; in the effluent, 7 to 61; at the tap, 6 to 34.

In 1903, the river water averaged 12,900, and the effluent 32, showing a bacterial efficiency of 99.7 per cent.

The management of the beds requires, of course, careful supervision, but the amount of actual labor is comparatively slight, each of the twenty-five beds requiring, on an average, not more than sixteen scrapings annually.

Slaughter of the Innocents.—According to a statement made by Prof. H. W. Wiley, of the chemistry bureau of the Department of Agriculture, more than a million infants have been sacrificed to the various concoctions known as soothing syrups and pain killers, and more than twice that number have been killed by impure milk.

Glycosuria in Pregnancy and the Puerperal State.—Bini says that glycosuria in the pregnant and puerperal state is not constant, and is even quite rare. It is a true glycosuria, since out of twenty-nine cases examined by the author, it was found in two cases only that lactose appeared in the urine, while in the puerperal patients there was glucose and lactose; the glucose disappeared rapidly, the lactose disappeared after a few days in those who were not suckling their children, while in those that were nursing it remained for some time. The author interprets this glycosuria as of spontaneous alimentary nature, from alteration of metabolism generally dependent on pregnant intoxication directly, and collaterally from all such causes as dyscrasia, alimentary troubles, etc.—*La Riforma Medica.*

Juvenile Glaucoma Simplex Associated with Myasthenia Gastrica et Intestinalis.—John Green summarizes the history of a case of this nature: A young woman free from hereditary ocular taint and afflicted with chronic constipation, which began in earliest childhood, was attacked shortly after puberty with glaucoma simplex. In one eye the failure of vision was progressive, and resulted in blindness. Near work was found to be impossible on account of ocular pain and blurring. Finally the vision of the fellow eye began to fail and she sought relief. Treatment with myotics over a period of several months failed to check the progress of the disease. General treatment directed against the constipation was instituted. Improvement in the general condition was accompanied by a like amelioration in vision, in the ability to use the eyes, and later by a widening of the field. The writer says that inferences drawn from the study of a single case are admittedly of little value. He states that we must be content in this case with noting the facts, which to his mind, were at least highly suggestive of an immediate etiological relationship between the constitutional and ocular condition. Constipation has been, indeed, accorded a place among the possible contributing constitutional causes of glaucoma (Treacher Collins); but in this case the assumption of a more intimate relationship has seemed not unjustified. As to treatment, the writer thinks that ophthalmic surgeons are pretty well agreed that in the acute and chronic congestive types of this affection operation is imperatively indicated. He again calls attention to the lesson which this case enforces, namely, that certain of the problems which confront the specialist can be satisfactorily solved only by collaboration between the specialist and his brother in general medicine.—*St. Louis Courier of Medicine.*

Pseudokousma.—Frank H. Koyle defines pseudokousma as that condition in which there is false perception of pitch. It is to be differentiated from diplacusis. The writer gives a brief review of the functions of the various tympanic functions concerned in hearing, laying particular stress on the tympanic cavity and mastoid cells in their capacity as resonance chambers. He shows how these functions are influenced by structural changes involving the sound-conducting and auxiliary apparatus. He cites two cases, with details of the history and treatment of each, together with a series of tuning-fork experiments. In one of these cases the immediate cause of the false hearing is ascribed to a rupture of some or all of the fibers of the stapedius muscle. In the absence of the stapedian curb, there is permitted an exaggerated pressure from without inward, and a condensation of the intratympanic air, resulting in a profound disturbance of the labyrinthine elements. The compressed sound-conducting fluid of the labyrinth is immediately responsible for the altered character of certain sounds, the muscle lesion being the causative factor. A relative inhibition of energy in the molecular impact takes place as a result of continued abnormal propulsion in a spirally compressed fluid, the increase in pressure causing a deviation from the curvilinear direction normal to the fluid contents of the structure. The writer states that it would seem that the degree of variation for a given tone in the scale will depend upon the degree of compression existing in certain area in a corresponding turn of the cochlea.—*Buffalo Medical Journal.*

MEDICAL RECORD.

A Weekly Journal of Medicine and Surgery.

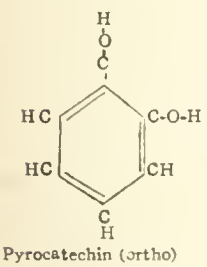
New York, March 24, 1906.

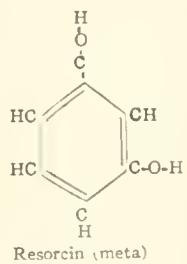
DIFFERENCES IN THE ACTION OF ORTHO-, META-, AND PARA-COMBINATIONS.

INVESTIGATIONS have proven that there exists a difference in the toxicity of ortho-, meta-, and para-compounds, and that as a rule the para-compounds are more powerful poisons than either of the other two. There are exceptions to this rule, as will be seen later. Why this should be, no one has as yet explained, nor shall we attempt to explain it here. We merely wish to call attention to these mysterious differences and to give some illustrations. As in the case of tissue selection and the effect that the weight of a molecule has when applied therapeutically, much remains for the present at least inexplicable, but that these several factors do very materially influence the physiological and pathological action of remedial agents is proven. In order that the reader may more clearly comprehend the meaning of the terms ortho, meta, and para, as applied to chemical products, it will be well to call attention to the theoretical molecule, represented by the following figure:

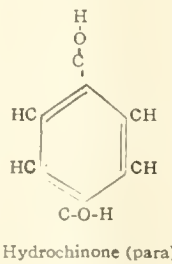
The figures refer to the different positions, or play of affinity. The benzene molecule is represented by a hexagon figure with CH at each angle, having thus the formula C_6H_6. When a sign is attached without a connecting line to any angle of the hexagon, it indicates that the body represented is substituted for the hydrogen at that point and the product thus becomes an ortho-, meta-, or para-compound, according as it enters at either of these positions. A substitution at 1 : 2 will mean an ortho, 1 : 3 a meta, and 1 : 4 a para-compound. Let us illustrate this in detail thus:



Pyrocatechin (ortho)



Resorcin (meta)



Hydrochinone (para)

Now, wherein do these several products differ physically, physiologically, or pathologically?

Pyrocatechin, the ortho-compound, occurs in flat crystals or plates, readily soluble in water, alcohol, and ether; it reduces silver salts in the cold and Fehling's solution on warming; if made alkaline, it absorbs oxygen and turns green; it has weak acid properties. Contrary to the rule above mentioned, this is the most toxic of the series. The fatal dose per kilo of body weight is 0.06 gm., of hydrochinone 0.1 gm., and of resorcin 1 gm. per kilo. Resorcin, the meta-compound, is found in colorless crystals melting at 100° C., boiling at 276° C.; very soluble in water, alcohol, and ether, with a sweetish taste. It is a powerful antiseptic and antifermentative. Hydrochinone, the para combination, is moderately soluble in water, easily so in alcohol and ether, occurs in six-sided prisms, fuses at 169° C. It is antipyretic and antidiarrheal in doses of 5 to 8 grains.

Again, we have orthocresol, a crystalline solid, fusing at 31° C. and boiling at 185° C. This exerts a paralyzing effect upon the heart in small doses. It irritates the nervous substance of the inhibitory apparatus and in larger doses it is a powerful tissue poison. Metacresol is a liquid boiling at 195° C. This is but a faint heart poison, does not affect the inhibitory apparatus, but acts rather upon the vasomotor system. Paracresol, a solid fusing at 36° C. and boiling at 198° C. This is also a cardiac poison, and acts secondarily upon the nerves. All these cresols tend to paralyze the sensory and motor systems.

There are exceptions to the rule that the para-compounds are more poisonous than either the ortho- or meta-, as was noted in comparing the toxicity of the dihydroxybenzenes (pyrocatechin, resorcin, and hydrochinone). Another illustration is furnished by the fact that para- and meta-oxybenzoic acids are both inactive, while the ortho-compound, known as salicylic acid, exerts an energetic action.

In the nitrophenols the para-compound is most poisonous, the meta- next, and the ortho- the least. All of these substances kill by paralyzing the heart; they exert no influence upon body temperature. The point of action and mode of action are the same, despite difference in the positions of the groups. One difference exists, however; the ortho- and meta-compounds irritate the vagus, while the para-compound weakens the action of the vagus.

The nitroanilins show a decrease of toxicity from para- to meta- and ortho-compounds. There are symptoms of anilin poisoning, formation of methemoglobin in the blood, and marked cardiac paralysis. All show an irritant effect upon the peripheral distribution of the vagus. The para-compound is ten times as poisonous as the ortho-combination.

The three isomeric toluidins are alike in their physiological action. All act destructively upon the red blood coloring matter from which they form methemoglobin. They paralyze the cord and cause death by arrest of respiration. Injected into the jugular vein of dogs, the fatal dose of orthotoluidin is 0.208 gm. per kilo body weight, that of meta-toluidin is 0.125 gm., and that of the para-combination, 0.1 gm. A striking illustration in the difference in these products dependent upon the substitution position is furnished in the benzoates of sulfinide.

The orthobenzoate of sulfinide, known to commerce as saccharin, is five hundred times as sweet as sugar, while the para-compound is tasteless.

Chemists are familiar with these differences and are thus enabled to build up at will products which exercise a predetermined physiological and pathological effect.

THE PATHOGENESIS OF PULMONARY TUBERCULOSIS.

When the discovery of the tubercle bacillus was announced it was generally thought that the question of tuberculous infection was solved and that the entrance of the germ was sufficient to produce a tuberculous inflammation in any given organ. It was soon demonstrated, however, that this view could not be accepted without certain modifications, particularly as regards the prèdisposition exhibited by the pulmonary apices, and that a number of other factors must therefore be concerned in the process. During the period when the inhalation theory was in vogue, the predilection of the apices of the lungs to tuberculous inflammation was first ascribed to certain peculiarities in the branching of the bronchial tree, and later on to a localized respiratory insufficiency. It was then asserted that the tissues of this region were less resistant to infection, because their blood supply was poorer than that of the rest of the lung, owing to the action of the force of gravity. This seemed disproved by the fact that in certain susceptible animals whose thoracic contents were maintained in a position more or less like those of man, such as the monkey, the kangaroo, and the giraffe, no such predisposition existed. All endeavors to solve this question by a resort to anatomical principles has thus far failed in their object. The interesting suggestion is now made by L. Hofbauer in the *Wiener klinische Wochenschrift*, No. 6, 1906, that a physiological rather than an anatomical explanation must be sought for in accounting for the difference in the pathological relations between the apical and the basal portions of the lungs.

Under ordinary circumstances, quiet, normal respiration in the human subject is accomplished in great part by the lower portions of the thorax, and even here the movements of the diaphragm play the most important rôle. The upper segments take very little part in this action, and the respiratory function, as has been proved by numerous observers, is exercised to a large extent, at least, by the lower thoracic segments. This difference in the activities between these two portions of the lung not only interferes with complete and thorough aeration of all the pulmonary alveoli, but the resulting disturbance in the equality of the intrapulmonic pressure likewise produces an unfavorable effect on the lymphatic circulation of these organs. There is a law in physics which states that the pressure in any closed space with communicating chambers is always equal in all parts of the same, and this would apparently contradict the idea that all portions of the pulmonary cavity are not equally aerated by the excursions of the diaphragm. Numerous experimental observations have shown, however, that variations in pressure starting from some particular portion of the lung do not progress very much beyond their point of origin. This is probably due to the manner in which the component branches of the bronchial tree radiate and also to the position of the connective-tissue septa.

There is every reason to believe, therefore, that the functional differences of the various thoracic segments agree very closely with similar differences in the corresponding portions of the lung. And so, in passing from below upwards, we find that during ordinary quiet breathing the respiratory movements of the thoracic wall are steadily diminishing in extent until a minimum degree is reached at the apex. This fact is sufficient, according to Hofbauer, to account for the circumstance that the basal are better aerated and nourished than the apical portions of the lungs, and so a greater resistance is interposed by the former to the penetration and growth of the tubercle bacillus, which simply settles where conditions are more favorable to its development. Before admitting the truth of this claim, one is tempted to ask why this same process of resistance should not be exercised against other pulmonary infections, such as the ordinary lobar pneumonia, whose favorite initial site is in the lower lobes of the lungs.

The Rectal Injection of Ether Vapor.

The sequelæ, oftentimes dangerous as well as unpleasant, which attend the administration of ether as an anesthetic, have prompted the introduction and use of numerous adjuvants and substitutes. The respiratory apparatus is most often affected by the drug as the result of the usual manner of oral administration, and the complications to be dealt with include respiratory disturbances, depression of the cardiac reflexes, resulting from irritation of the laryngeal or bronchial mucous membranes, pneumonic processes, etc. Attempts have been made in great number to overcome or at least to diminish these effects of ether by the preliminary administration of nitrous oxide, ethyl chloride, etc. Another suggestion in an entirely different vein was made as long ago as 1847 by the well-known surgeon, Pirogoff, in Paris. He proposed, in place of the inhalation of ether, its introduction in vapor form into the rectum for the purpose of inducing general narcosis. The method did not meet with any enthusiastic reception, but from time to time it is revived or is suggested independently by some one who has not heard of the previous attempts in this direction. Some fifteen years ago the method was revived in Denmark, and was received with favor by surgeons all over the world. It fell again into desuetude, and now a Russian military surgeon, Dr. Krugiline (*Der Frauenarzt*, December 15, 1905), writes that he has used it altogether in 43 cases requiring operations of moderate severity and extent, such as harelip, bone tuberculosis, hernia, lupus, etc. Two conditions must be fulfilled in order to insure the success of this procedure: the colon must be absolutely empty and no fluid ether must be permitted to enter the rectum, as the mucosa of the latter is particularly sensitive. This can readily enough be avoided by the use of a properly constructed apparatus. If thorough catharsis has not been obtained the entrance of ether into the rectum will produce unpleasant symptoms, especially an annoying tenesmus. Ordinarily, however, with an empty colon, sensation is lost in from two to three minutes, and the odor of ether may then be detected

in the breath. Narcosis is soon complete, the pupils become contracted to a marked extent and do not react to light, but as a general rule the corneal reflex remains. The writer is quite enthusiastic regarding the advantages attendant upon this method, the narcosis being produced rapidly and the usual respiratory difficulties being avoided; he also claims that there is no period of excitement, and no reactionary symptoms are noted. For all ordinary cases the narcosis produced by this method was found to be sufficiently deep, but if not, the intermittent inhalation of a few drops of chloroform was enough to make it so. Although particularly adapted for operations upon the head and neck, Dr. Krugiline thinks that the method may be used with equal advantage in other cases, the only apparent contraindication being furnished by intestinal inflammations and ulcerations, and peritonitis. It is not likely, however, that this suggestion of the rectal administration of ether will be taken up with any great enthusiasm so long as the generation of surgeons who once tried it and abandoned it is still living.

Yaws and Syphilis.

The relationship between these two diseases has been the subject of numerous discussions among physicians interested in tropical medicines, some claiming that yaws is merely a form of syphilis, others that it is quite distinct. The accumulating observations of recent years seem to show, however, that the two diseases are different and this distinction seems to be supported by the geographical distribution, the clinical symptoms, and the histopathology of these conditions. As pointed out by Castellani (*Journal of Tropical Medicine*, January 1, 1906), who has made a special study of the disease in Ceylon, syphilis is pandemic, while yaws is localized in certain parts of the tropics, the nearest point to our own shores being in the West Indies. There are other contrasts, moreover, between yaws and syphilis which stamp them as distinct diseases. The primary sore, if it may be so called, of yaws is generally extragenital; the eruption is of the papular variety and may proliferate into a papillomatous growth; there is an extremely well marked pruritus. In yaws, moreover, sequelæ comparable to tertiary syphilis or parasyphilitic conditions are absent or extremely rare, neither is this disease hereditary or congenital. The study of the bacteriology of the disease brought forth some interesting developments. All sorts of bacteria were found, including cocci, sarcinæ, and bacilli, but in a majority of the cases Castellani isolated an organism which could not be distinguished from *Spirochæta pallida*. This observation has also been confirmed by Wellmann and by Powell in other cases. If future investigations prove that yaws is a spirochete disease, its germ will have to be distinguished biologically from the spirochete of syphilis. An analogous situation may be traced in the morphological similarity between the leprocy bacillus, the tubercle bacillus, and many other acid-fast bacteria; yet leprosy is not considered to be tuberculosis. It is also practically impossible to distinguish morphologically the surra from the nagana trypanosome, but the two diseases are nevertheless different. Castellani has found that antisyphilitic treatment is effective also in yaws, yet it is asserted that some cases may recover spontaneously. In all stages of yaws, however, he has found large doses of potassium iodide more effective than mercury. This cannot be used as an argument for stamping the disease as syphilitic in character, for we have another instance of the beneficial effect of the iodides in a disease quite different from syphilis, namely, actinomycosis.

The Effect of Changes of Temperature on the Viscosity of the Blood.

It is an interesting question whether it is possible to alter the viscosity of the circulating blood by changing the temperature of the surrounding medium. R. Burton-Opiz (*Journal of Experimental Medicine*, Vol. VIII, No. 1), who had previously studied the effect on the viscosity of defibrinated blood, has now directed his attention to solving the behavior of "living" blood in this respect and has made a number of experiments in dogs for this purpose. The effects of warm and cold water baths and of hot dry air were tested. As regards the effects of the bath, it was found that the viscosity of the blood reacted very sharply toward changes in the temperature of the surrounding medium, it being decreased by warm and increased by cold water baths. The greatest change took place during the first ten or fifteen minutes of the bath, and the effects were equally pronounced with cold as with hot water. The specific gravity of the blood pursued a course parallel to that noted for the viscosity, warm water baths producing a decrease and cold water an increase in the specific gravity, the changes being very pronounced in both cases. Hot air baths did not render the blood less viscous, as one might suppose, but rather more so. Comparing them with the warm water baths it was seen that the two produced directly antagonistic results, although the former was less powerful. The specific gravity of the blood became greater during the hot air baths and there seemed to be a direct relationship between this and the viscosity. These results constitute an interesting addition to our knowledge of the theories of physical therapeutics.

News of the Week.

Seaside Park Bill.—On March 15 the Assembly Cities Committee framed a substitute bill for the Tompkins seaside park bill which was discussed in the Medical Record of March 3. The bill authorizes the Board of Estimate to appropriate $1,500,000 for the purpose. Care of the park is devolved upon the Park Department. With the approval of the Sinking Fund Commission the Board of Estimate is also to have the power to withdraw from the jurisdiction of the Park Department such portion of the park as it deems proper for a period of not exceeding twenty-five years, and to allow its use by any charitable or benevolent society that will erect a convalescent hospital thereon. No insane or persons affected with a contagious disease are to be received and maintained in any hospital in the park. Provision is also made to enable the Board of Estimate whenever it has appropriated a sum sufficient for the erection and maintenance of a hospital in the park, to withdraw from the jurisdiction of the Park Department any portion of the park it may deem proper and confer jurisdiction over the same on the Board of Health or the trustees of Bellevue and allied hospitals, or the Commissioner of Charities.

Dr. H. N. Heinemann, formerly of New York, who has been ill, is now, his friends will be glad to learn, fully restored to health and has resumed his practice in Nauheim.

Dr. Thomas Watts Eden of London was the guest of honor at a dinner given by Dr. J. Clifton Edgar at the University Club on Wednesday evening of this week. There were about sixty guests, including many prominent obstetricians of this and neighboring cities, and other medical men.

Patent Medicine Formulæ.—At a hearing before the Senate Committee at Albany to consider the Stevens bill, which was described in these columns last week, several amendments were inserted. The chief amendment was one making it a felony to sell opium or cocaine without a physician's prescription, and a felony also for a physician to prescribe it unless it shall be for purely medicinal use. Much stress was laid by those appearing before the committee on the dangers of the indiscriminate sale of opium and cocaine preparations, and this amendment was the result.

Yellow Fever.—The New Orleans Board of Health has announced that a patient supposed to have yellow fever is under treatment in the Charity Hospital. This is the first suspicious case observed since last autumn. No one has yet been able to claim the prize offers of $5 for the first person to bring a live stegomyia mosquito, $3 for the second, and $2 for the third. People have come from all about bringing all sorts of insects, even water bugs, in bottles, but the offer is still open, as no genuine stegomyia has been found.

The Smoke Nuisance.—Seventy-five warning notices have been or are being issued by the Board of Health to firms whose smokestacks have been emitting smoke of improper nature. It is promised that if when a reinspection is made five days after the receipt of the orders the nuisance is still unabated, the Board of Health will use the authority vested in it to compel obedience.

Immunity from Smallpox.—Chief Medical Inspector of the Chicago Health Department, Dr. Heman Spalding, is credited with saying that the certain efficacy of vaccination in preventing smallpox accounts for Chicago's immunity from the disease this winter. This is apparent, for the disease is all about in neighboring towns and cities, as it was in each of the past seven years, when the disease found lodgment, but it has gained no foothold in Chicago. Continuous efforts to secure the vaccination of everybody in Chicago have been made by the department, and with gratifying success. Chicago is said to be now one of the best vaccinated cities in the United States. There are still enough unvaccinated, however, to make it necessary to be aggressive and vigilant in enforcing the vaccination ordinance, lest the unprotected increase in number. Dr. Spalding urges that there be no abatement in vaccination, because smallpox is not killing by the hundred. Laxity in the matter of vaccination is sure to reap its harvest, as it has many times in the past. To continue free from smallpox, the people of Chicago must be kept vaccinated.

Philadelphia Clinic for the Home Treatment of Consumption.—A clinic has been founded in Philadelphia for the purpose of combating tuberculosis among the poor, not only by direct medical treatment but also by supervision of the living quarters, instruction in hygiene and sanitation, etc. Daily clinics will be held between three and four every afternoon, except Sundays, at 519 South Fifteenth street, for the treatment of all chest troubles in patients who are able to walk. Patients of the same class who are unable to walk, and who are not under medical care, will, by giving notice to the clinic, be visited by a physician, and by a nurse if necessary. Medical services and nursing are free, but a nominal charge for medicine is made to those who are able to pay. The territory to which the work will be confined at first is divided, and each district will be assigned to a physician and nurse. The members of the medical staff are: Dr. Thomas J. Mays, Medical Director, Dr. John D. McLeon, Dr. Ralph H. Spangler, Dr. J. P. Bethel, Dr. Andrew D. Carter, and Dr. Arthur C. Wolfe.

The Lisbon Congress.—The executive committee of the Fifteenth International Medical Congress announces that a considerable number of rooms with one or more beds have been reserved for medical visitors at prices ranging from six to ten francs per bed. Pension rates are fifteen francs a day for each person. Accommodations will be assigned in the order of the reception of applications by Mr. Manuel José da Silva, Palacio Foz, Praça dos Restauradores, Lisbon. Arrangements have been made with the French, German, Italian, Spanish, and Portuguese railroads through which those attending the Congress will be given a reduction of 50 per cent. in fares, and will be permitted to take different routes in going to and returning from Lisbon.

Bequests to Charity.—By the will of the late Edward T. Dobbins of Philadelphia, the sum of $3,000 is bequeathed to the Woman's Medical College of Pennsylvania, for the endowment of a free bed; an additional sum of $3,000 to the same institution to pay the tuition for the regular course of instruction in medicine of a young woman who can pass the necessary examination, preference being given to a graduate trained nurse; $5,000 to the Burlington County Hospital; $5,000 to the Children's Hospital; $5,000 to the Home for Incurables; $2,500 to maintain a scholarship at the Philadelphia College of Pharmacy to be conferred upon a New Jersey apprentice passing the highest preliminary examination; $10,000 to Christ Church Hospital, and $10,000 to the Hospital of the Women's Medical College.

Hospitals vs. Libraries.—Twenty-one hundred citizens of Mansfield, Ohio, have signed petitions requesting that the Carnegie library building, now in course of erection, be made into a city hospital, and that the ten thousand dollars already advanced by Mr. Carnegie be returned to him unless he should be willing to have the building used as a hospital. The petitioners say that the city needs a hospital more than it needs a library.—*Lancet-Clinic.*

Gifts to St. Luke's Hospital of Chicago.—Mr. J. Ogden Armour has given $25,000 toward the $140,000 required for the new George Smith addition to St. Luke's Hospital (Chicago). Of the required amount it is said that $80,000 is at present in the treasury.

Dr. Robert T. Morris on March 14 delivered a lecture on "A Naturalist's Camping Trip to Hudson Bay," before the Linnæan Society of New York City at the American Museum of Natural History.

Louisville Academy of Medicine.—At the meeting of the Louisville Academy of Medicine, which took place March 7, 1906, the following officers were elected: *President*, Dr. J. T. Windell; *Vice-President*, Dr. D. R. Jacob; *Secretary*, Dr. O. H. Kelsall; *Treasurer*, Dr. Gavin Fulton. The guest of honor was Dr. Lewis S. McMurtry, the president of the American Medical Association.

Cincinnati Academy of Medicine.—At the meeting of this organization held on March 5 the following officers were elected: *President,* Dr. John E. Greiwe; *Vice-Presidents,* Dr. Henry Bettman and Ellen McCarthy; *Secretary,* Dr. Stephen Cone; *Treasurer,* Dr. A. G. Henry.

Fire at the General Memorial Hospital.—The catching fire of a supply of hay in the ambulance stable of the General Memorial Hospital, New York, one day last week made it necessary to go through the fire drill and send in an alarm. The hospital employees had the blaze under control before the firemen arrived, and but little damage was done.

Attack in a Hospital.—As the result of a recent railroad accident twenty-one injured men are being cared for at the Westmoreland Hospital, Greensburg, Pa. Some of their fellow laborers, Italians and Austrians, living in barracks at Rodebaugh, became enraged because no visitors were allowed to see the patients, and assembling in force stormed the hospital for several hours. Attempts were made to force the doors and many missiles were hurled. The local police managed to hold the doors till the State constabulary could be summoned.

Tuberculosis Exhibition.—The University Settlement, the College Settlement, and the Recreation Rooms and Settlement on March 14 opened their joint tuberculosis exhibition at the Recreation Rooms, 186 Chrystie street. On the different evenings of the exhibition, which lasted four days, popular addresses were made in English, Italian, and Yiddish.

Royal Medical and Chirurgical Society.—At the meeting of this society held on March 1 Mr. J. Warrington Howard was elected president for the ensuing year.

Bubonic Plague is said to have reappeared in New South Wales, and five cases have been reported from Sydney.

The Sand Cure.—From Toledo, O., comes the story of a man of 88 who is youthful enough to break in yearling colts, and considers that his good health is largely due to occasional teaspoonful doses of well-washed sand. Fifteen years ago he developed some gastric affection which did not yield to medical aid, and in his efforts at self-treatment he finally hit upon the idea of taking the sand. The measure was promptly followed by an abatement of the symptoms and has continued to do so whenever he feels that a recurrence of the difficulty is imminent.

The Poison of the Borgias.—According to a newspaper dispatch several young Russian women who are students at the university of Turin are being kept under surveillance by emissaries of the Russian secret police because they are suspected of being engaged in attempting to discover the secret of the *aqua tofana,* the mysterious poison said to have been employed with such success by the Borgias. On the occasion of a rather serious illness suffered by the Tsar some years ago it was alleged that he had been poisoned by means of a pair of gloves impregnated with one of the old Italian poisons, the composition of which had been rediscovered by Russian revolutionaries by search among the old manuscripts in which the Biblioteca Nazionale at Turin is especially rich.

To Remove State Tax on Virginia Doctors.—Dr. Powell's bill removing the State license tax of $10 a year now imposed on practising physicians in Virginia was passed by the House on March 8 by a vote of 52 to 29.

Operating Under Difficulties.—In consequence of a fire which did $15,000 worth of damage to the building, seventeen patients in the Trull Hospital in Biddeford, Maine, had to be removed to places of safety. When the fire was discovered an operation was under way on a female patient, and as the operating room was in danger of being invaded by the flames the patient was carried to the ground floor where the surgical procedure was completed. It is stated that owing to the leakage of water through the ceiling from the rooms above it was necessary to have umbrellas held over the operating table in order to protect the wound.

Absinthe in Belgium.—Several efforts have already been made to abolish the use of absinthe in Belgium, but the opposition of the manufacturers and retailers involved has always been too strong. A short time ago, however, a prohibitory bill passed both houses of the legislature, and from now on the importation, manufacture, transport, sale or storing for sale of absinthe or of any substitute for it is illegal. The penalties are substantial.

Obituary Notes.—Dr. William T. Bacon of Hartford, Conn., died on March 17 at the age of sixty years. He was well known as a specialist in diseases of the eye and ear.

Dr. Leopold Hirschmann of New York City, died on March 15 at the age of thirty-five years. Dr. Hirschmann was born in Germany but had lived in New York for sixteen years. He was a graduate of Cornell University Medical School.

Dr. Lawrence J. Gerold, assistant surgeon of the State Soldiers' Home Hospital at Bath, N. Y., died March 15 of heart disease. He was forty-one years old and was formerly assistant physician at the State Hospital, Kings Park, L. I.

Dr. John P. Henry of Jersey City, died on March 16 in a private hospital at Paterson, N. J. His illness was due to overwork. Dr. Henry was born in 1858 and was graduated from the College of Physicians and Surgeons in New York in 1881. Three years later he was appointed a city physician of Jersey City and served as a member of the Board of Health for a number of years.

Dr. Peter V. P. Hewlett of Newark, N. J., died March 13 at the age og fifty-nine years. He was graduated from the College of Physicians and Surgeons in New York in 1871 and began to practise in Newark the following year. He was county physician of Essex County for several years and was prominent in the management of the City Hospital. About a year ago he became infected in the course of an operation and was obliged to give up practice on this account.

Dr. Everett Hasbrouck of Brooklyn, died on March 16 in his sixty-sixth year. He was a graduate of the Long Island College Hospital and of the New York Homeopathic Hospital. He had practised in the Windsor Terrace district for over twenty years.

Dr. Henry T. Calkins of Petoskey, Mich., died on March 5 at the age of sixty-six years. Dr. Calkins was born in Germantown, N. Y., and received his medical diploma in Louisville, Ky., in 1860. After two years of service in the army as assistant surgeon he located in Grand Rapids but removed to Petoskey in 1878, since which time he had occupied many public positions.

Dr. William H. McCormick of Cumberland, Md., died on March 6 at the age of eighty years. He was born in Fayette County, Penn., and was graduated from the Jefferson Medical College of Philadelphia in 1849. In 1863 he located in Cumberland, and since that time had filled many professional and public positions. He was one of the founders of the old Alleghany County Medical Association and was one of its presidents; and was twice president of the Jefferson Medical College Alumni Association. He retired from active practice about ten years ago.

Dr. Jewett Williams, Jr., Adrian, Mich., died on March 9 after an illness of several weeks which had its origin in an injury to the pelvis caused by a blow from the crank of his automobile. He was graduated from the Detroit Medical College in 1890 and in 1895 took a course in the New York Postgraduate Hospital. Dr. Williams was forty-three years of age.

Dr. S. R. Hewitt of Dubuque, Ia., died on March 5 of heart failure at the age of seventy-six years. He was graduated from the Rush Medical College in Chicago and had practised in Floyd County since 1859.

Dr. J. M. Selfridge of Oakland, Cal., died on March 3 at the age of eighty-two years. He was born in New York State, but after completing his medical education went to California in 1852 where he practised until 1856. He then went to Philadelphia for a year of postgraduate study, and returned to California, where he had practised ever since. He was twice president of the Homeopathic Society of California and was attending physician to the State Institution for the Deaf, Dumb, and Blind from 1872 to 1878.

Dr. Mabel Wells, formerly of Monticello, Ark., died on March 3 in Wellesley, Mass. She was graduated from the medical department of Johns Hopkins University and was thirty-two years old.

Dr. L. T. Holland of Los Angeles, Cal., died on March 6 at the age of sixty-three years. Dr. Holland was graduated from the Missouri Medical College and had practised in California about twenty years. He served for a number of years as coroner and as a member of the Board of Health.

Correspondence.

OUR LONDON LETTER.

(From Our Special Correspondent.)

GASTRIC SURGERY—INTESTINAL CASES—OSTEOARTHRITIS IN DISGUISE—X-RAYS AT CAMBRIDGE—TO HONOR THE DISCOVERER OF COAL-TAR COLORS—DEFECTIVES—CARE OF TEETH.

London, March 2, 1906.

Gastric surgery has been very prominent of late, and I have reported the expressed views of several of its most able exponents. Now we have the Hunterian lectures for this year at the Royal College of Surgeons devoted to the subject, the professor being Mr. Herbert J. Paterson, who is one of the surgical staff of the Temperance Hospital. It is impossible to take note of the various conditions and surgical procedures discussed in this course, and many of them have had a place in my former letters. I will, therefore, confine myself to "Hour-glass Stomach," which Mr. Paterson treated with much acumen. The condition, first accurately described by Morgagni, may be present to a great degree and give little indication on the exterior surface of the stomach. In one case, the lecturer said, there was only slight puckering, but internally an annular stricture admitted only the tip of his little finger. He supported the view of Mayo, Robson, and Moynihan, that the congenital variety has probably no existence in nearly all recorded cases, ulceration or its consequences having been found. No case has been recorded in a fetus. Some so-called congenital cases may be explained by an incident related: At a postmortem an apparently typical specimen of hour-glass stomach was found, and by an oversight was not put into a hardening reagent. On examining it next day, Mr. Paterson found all trace of constriction vanished, and presumably it was only a muscular contraction persisting after death. Had it been put into the hardening solution, "doubtless I should have presented it before you to-day as a typical example of congenital hour-glass stomach."

As to treatment, the lecturer had collected ninety-two operations for non-malignant hour-glass stomach, and ascertained the after-results in sixty-one out of the seventy-six patients who survived the operation. The several procedures had been: (1) Gastroplasty (in some cases with resection of the ulcer); (2) gastroenterostomy; (3) gastrojejunostomy; (4) gastroduodenostomy; (5) dilatation. Combined operations have sometimes been required and carried out. The importance of examining the whole stomach from the esophagus to the duodenum was emphasized by reference to two recorded cases in which the pyloric pouch was mistaken for the whole stomach. In some cases two constrictions existed, dividing the stomach into three pouches (the trifid stomach). Sometimes pyloric stenosis complicates the case, and if then gastroplasty only is performed a further operation may be necessary, as in one recorded case. Of the ninety-two cases collected by the lecturer, sixteen died of the operation and seventy-six recovered. Of the fatal cases, some were worn out by prolonged pain and vomiting. In three the pyloric pouch was mistaken for the whole stomach and gastrojejunostomy performed on the pyloric side of the constriction. In two, death occurred from septic peritonitis, in one from perforation of another ulcer, and one died from hematemesis a month after operation. These and other statistics were considered at length and set out in tabular form, the conclusions arrived at being that: Gastroplasty is the simplest plan, but is open to the same objection as pyloroplasty for stenosis of the pylorus, viz., frequent relapses. In at least 25 per cent. no relief followed or there was relapse later, especially when there was active ulceration at the time of operation. It was pointed out that this operation is not a preventive of ulceration, nor does it modify predisposing conditions. Further, adhesions are often present and impair motility, and keep up gastric stasis, leading to hyperchlorhydria. The same criticisms apply to gastrostomy, from which 30 per cent. either got no relief or relapsed. It was therefore suggested as advisable, when either of the preceding operations were performed, to do a gastrojejunostomy at the same time. Only two of the patients on whom this last was performed had recurrence of symptoms, and one of these was due to coexistent pyloric stenosis, while not one out of eight patients on whom the double operation was performed had had so far any sign of relapse. Possibly anastomizing a loop of jejunum to both the cardiac and pyloric pouches would be a simpler plan, and that does not necessitate cutting the diseased area. Whatever details may be modified, it would seem that gastrojejunostomy must form part of the method adopted. In hour-glass stomach, as in so many gastric disorders, that is our sheet anchor.

Intestinal cases occupied the Clinical Society on Friday. Mr. Sherrin first related three unusual cases of obstruction. One was a man of thirty-one, who had a stricture at the junction of the jejunum and ileum. Enterostomy, followed by enterectomy three weeks afterward, led to recovery. The second case was in a girl of thirteen, caused by left duodenal hernia and reduced seven hours after onset of symptoms. She recovered. Only ten similar cases have been recorded, six of them fatal. The third case was volvulus of the cecum in a man of thirty-one, operated on seventeen hours after onset of symptoms. The cecum was gangrenous, and resection was performed, with anastomosis of ileum to ascending colon. These cases seem as rare as they are interesting.

Mr. Hutchinson, Jr., had lately seen volvulus with great laxity of the mesentery, under which the cecum had passed and was found near the spleen. The patient, a young man, recovered.

Mr. Raymond Johnson referred to a case in which a twisted and distended cecum passed under the small intestine. He untwisted and aspirated, but the man (aged 49) died within twelve hours.

Mr. Spencer related a fatal case of twisted cecum in an old man. It was found near the spleen.

Mr. Barker mentioned a case he had published, in which the small intestine had twisted round a gastroenterostomy union. He thought duodenal hernia more frequent than usually supposed.

The next contribution was by Mr. H. W. Carson on two cases of appendicitis associated with oxyuris vermicularis. The first was in a woman of nineteen, seized suddenly,

brought to the hospital the next day, with temperature of 103, tenderness, etc. The appendix was removed and an oxyuris found. The mucous membrane was inflamed, but not ulcerated. In the second case, a woman of twenty-four, the temperature on admission was 100.6°, but pain and other symptoms more severe. In the appendix three worms were found. In neither case was there a history of thread-worms, and none had been seen in the motions since. Mr. Carson referred to Dr. Still's paper on two hundred necropsies of children under twelve, in which the oxyuris had been found in the appendix twenty-five times without symptoms. Worms had been reported in the appendix after removal thirteen times. He thought it more reasonable to believe they caused the appendicitis than that their presence was a mere coincidence. The president (Mr. Clutton) thought otherwise, as did Mr. Hutchinson Jr. The worms were rare, compared with the frequency of appendicitis.

Abscess of appendix with severe hemorrhages, in a woman of thirty-six, was the subject of the next communication, made by Mr. J. D. Malcolm. On the third and sixth days after evacuation of a foul abscess, which was drained, the bleedings occurred, the second producing collapse and unconsciousness. The wound was opened and much clot removed. The appendix was not found, the cavity was packed, and healed by granulation. Some recorded cases were referred to. The complication was attributed to sloughing induced by microbes in the bowel, and compared to secondary hemorrhage in preantiseptic days.

Mr. Clutton related a case in which continuous oozing occurred for fourteen days, starting on the fifth day after operation. It was not an abscess case. He thought it curious that secondary hemorrhage was so rare in appendix cases.

Mr. Spencer suggested as a reason that the hemorrhage was due to a special organism, Klein's *Streptococcus hemorrhagius*, in which he still believed.

Mr. Raymond Johnson had seen alarming hemorrhage in such a case in a boy of seventeen. The external iliac artery had been ulcerated and had to be ligated.

Mr. Seymonds many years ago saw death from this accident.

Mr. Hutchinson, Jr., quoted a series of cases (published in the *Bulletin de la Société d'Anatomie*) in which this accident preceded the operation. Many cases were fatal. He had seen one on the ninth day after operation. He suggested some might occur from the ligature on the meso-appendix slipping.

Mr. Wallis advocated the use of strong antiseptic gauze, but some surgeons dissented.

"Osteoarthritis in Disguise" was the title of a paper at the Æsculapian Society, by Mr. P. L. Daniel, which he illustrated by numerous skiagrams. Among the disguises in question he named sciatica, hallux vulgus, flatfoot, internal derangement of the knee joint, loose cartilages, bunions, lumbago, and all degenerative changes in joints and the surrounding tissues. An extensive list, you will say! A suffering doctor assures me the disease is quite capable of as many or more disguises. Mr. Daniel held that any toxemia might set up a joint affection, and if any joint were injured or inflamed, it the more easily suffered from any toxin. Skiagrams almost always showed some joint affection in sciatica, though no disease of the nerve had been found. Flatfoot was associated with change in the small joints of the tarsus, and so is bunion, for which he recommended passive exercise. Lumbago, he said, often resulted from affection of the sacroiliac or vertebral joints. Massage and slapping the back relieved by separating adhesions.

At the invitation of the professors in Cambridge University, Dr. Walsham inaugurated *x*-ray work with a lecture and demonstration with lantern slides from skiagrams, of the clinical value of this method of investigation. The most recent forms of apparatus were described, particular stress being laid on the importance of the exact measurement of both the quantity and quality of the rays emitted from a given tube. The splendid installation used for the lecture had been presented by Dr. R. C. Brown of Preston to the committee for the study of special diseases, the value of whose gift was acknowledged by Professors Allbutt and Woodhead as having put the committee in a position to begin *x*-ray work at once.

The Lord Mayor presided on Monday at a meeting to inaugurate a fund to honor Dr. W. H. Perkin, who fifty years ago, when only eighteen years of age, in the course of a research respecting quinine, discovered the dye-stuff known as "mauve." His discovery was the beginning of the great coal-tar color industry. Dr. Perkin had not himself capital to develop this industry, and English business men were as careless as usual of scientific discoveries, the ultimate result being that the invention passed to Germany and is producing millions a year. Now England proposes to present Dr. Perkin with a portrait to keep for his life and then to revert to the nation, to have a bust executed for the Chemical Society, and to establish a "Perkin Research Fund." Rather a feeble as well as a belated recognition—is it not?

Dr. John Macpherson, lunacy commissioner, Edinburgh, assured the commission on the feeble-minded that the administration of the lunacy act in Scotland was admirable, only needing attention to bring the deficit under proper care. Observation wards such as those in Glasgow should be established in all large centers and all cases in which there was any doubt sent to them to be watched. For the morally, though not markedly mentally insane, village asylums for various terms might be utilized. Parish councils should take charge of all neglected imbecile children. A wider recognition of insane conduct would bring inebriates, spendthrifts, and chronic delinquents under control.

Dr. Macdonald, superintendent Dorset Asylum, advocated the necessity of preventing reproduction by degenerates, and Mr. Bund, chairman of Worcester County Council, would provide homes in which the promiscuous multiplication of the deficient could not occur.

What with one sanitary organization and another the public is getting plenty of advice. At the Institute of Hygiene Dr. G. Norman Meachen has been lecturing on the mouth and teeth. He remarked on the discrimination of taste by the sides and tip of the tongue, its relation to smell and so on. Considering that only 14 per cent. of school children were reported by the committee of the British Dental Association as having good sets of teeth, free from decay, he felt there was need for inquiry into the causes. Neglect of the teeth in childhood was the most fertile source of dental caries. To protect them against the inroads of the one hundred or more species of germs found in the mouth nothing is more effective than mechanical friction with the too-neglected toothbrush.

OUR VIENNA LETTER.

(From Our Special Correspondent.)

THE ROYAL FAMILY—ACTION OF HORSE SERUM—A CANCER CIRCULAR—SKODA'S CENTENARY—AN UNUSUAL PUPILLARY CONDITION—EMPHYSEMA FOLLOWING MEASLES.

VIENNA, January 18, 1906.

OUR readers have probably learned from the daily press that the Austrian Royal Family have lately suffered severely from sickness. The Archduke Otto, whose chronic malady has for several years required prolonged courses of treatment, has been suffering from a perichondritis of the larynx of so grave a nature that tracheotomy became necessary on account of the danger of suffocation. The Archduke stood the operation well and is now on the road to recovery. His son, Archduke Karl, at one time heir presumptive to the throne, recently while skating was the victim of an unlucky accident which resulted in a fracture of both bones of the leg. The injury was examined under the *x*-rays and it was found that the fractured ends were in good position and without splintering, so that a good prognosis has been given.

Dr. Emil Körmörczi experimented with horse serum in treating erysipelas in Prof. Rona's clinic. As a result of these observations Körmörczi continued his investigations by injecting large amounts of the horse serum and reached the conclusion that when given in large quantities it is capable of producing pathological symptoms. Severe chills are caused, followed by an elevation of temperature lasting ten or twelve days; the patient's general condition is poor, the body weight falls, the glands and the spleen become swollen, and long persisting and obstinate diarrheas are observed. If the horse serum is used for therapeutic purposes it is important not to administer it in too large amounts. It is important to use only concentrated serum in order that small doses may be sufficient.

The Medical Association has distributed among all the physicians of Austria a circular intended to aid in the combat against cancer. The circular was drawn up by a committee of the society, appointed for the study of carcinoma. It calls attention to the fact that cancer is curable in most cases and that it can be definitely cured when taken at a stage when it is still a purely local disease. At the present time the most reliable method of treatment consists in the early and radical application of surgical measures. The circular also states that most cases of malignant disease do not reach the operator's hand until the disease is in so advanced a stage that the prospect of a radical cure is greatly diminished. While it is true that in many instances this delay is the fault of the patient, it cannot be denied that cancers often come to operation too late, owing to injudicious advice on the part of the medical attendant. Then follows a detailed account of the symptoms of beginning carcinoma as they are likely to be encountered by the practitioner. The satisfactory results attending the distribution among mid-

wives of a similar circular are also spoken of. It is stated that while before the appearance of this general caution 54 per cent. of the midwives consulted by patients acted incorrectly in either attempting to treat the women themselves or in not sending them promptly to the physician, after distribution of the leaflet of instructions this occurred in only seven instances. It may also be noted that the committee which induced the Medical Association to publish this warning to physicians is composed of the most prominent teachers of the University faculty and of practitioners of recognized ability.

On December 10 the Viennese medical world celebrated the day on which the inimitable clinician Skoda was born, one hundred years ago. Skoda, although he pursued his studies under the greatest hardships and met with much opposition in endeavoring to popularize the methods of percussion and auscultation, finally succeeded in having the correctness of his views universally recognized and caused Vienna in the years following 1838 to become the center of scientific medical study. His courses of lectures attained a world-wide reputation and attracted listeners from all parts of the world. Skoda died in 1881, of calcification and aneurysm of the aorta.

Dr. Schmeichler has reported an unusual pupillary condition. A twenty-year-old tinsmith three months previously fell from a ladder, and in addition to other injuries sustained a contused wound of the right temple, and cerebral concussion. The further course of his illness was not known, but on entering the room it was at once noticed that the left pupil was greatly dilated. As the man stated that he saw nothing with one eye it was assumed that he was blind on the left side, but this was found not to be the case, for on bringing the patient to the window both pupils became equal. On testing each pupil separately it was found that direct light thrown on the right pupil produced no reaction in either eye; on exposing the left pupil to light it contracted actively and there was a moderate consensual contraction of the right pupil. This remarkable phenomenon was explained on the use of the ophthalmoscope, which revealed well marked atrophy on the right side. The conditions present may be easily understood if in addition one assumes the existence of a congenital dilatation of the left pupil. Under ordinary conditions of illumination the left pupil was larger than the right, but in a bright light the left pupil contracted strongly while the right remained fixed, thus causing both to appear of equal size. The pupillary examination even without the ophthalmoscope showed that the cause of the blindness must be on the peripheral side of the optic chiasm, otherwise no consensual reaction of the right pupil would be possible.

Dr. Swoboda has described the case of a three year old girl suffering from subcutaneous emphysema following measles. The child was rather weakly, weighing only six kg., had a tuberculous family history, and was extremely rachitic. Seven days after the onset of the measles it showed marked swelling of the neck. This soon became extreme and spread to the rest of the body; the eyelids were puffed up to such a degree that for a week the child was unable to open them; percussion everywhere elicited tympanitic resonance and on palpation crepitation was felt. Placed in a bath tub the child floated like a cork on the surface of the water. The swelling subsided thirteen days later; on *x*-ray examination numerous tuberculous foci were detected in the lungs and it is likely that these lesions played some part in the production of the emphysema. The condition might be explained by assuming the rupture of dilated alveoli or cavities, permitting the escape of air into the interalveolar tissue from which point it spread to the hylus of the lung and into the mediastinal connective tissue; or superficial alveoli or cavities may have ruptured and the air may have entered the pleural cavity from these. Several similar cases have been reported in the literature.

The Employment of Oxygen in Surgical Infections.—M. H. Wohlgemuth communicates the good results which he has obtained from the employment of oxygen in the treatment of whitlow, furuncle, anthrax, and phlegmon. Thanks to repeated injections of oxygen, the writer has been able to arrest or shorten the evolution of the infection, and in every case he has been able to limit the suppuration. He has also avoided the necessity of large incisions. Thus the deforming scars so common after operations in such affections are prevented. The only inconvenience attaching to these injections of oxygen is their painfulness.—*La Presse Médicale.*

Progress of Medical Science.

Boston Medical and Surgical Journal, March 15, 1906.

The Open-air Treatment of Tuberculosis.—W. A. Griffin notes that in making patients take the open-air treatment there are certain points upon which stress should be laid. One is that the more nearly the treatment is kept for the entire twenty-four hours, the better. It is not sufficient that the patient should spend the day in the open air, but the windows should be open all night. There are various forms of shelter, but the best, other things being equal, is the simplest. The only necessity is that it shall keep out the wet. Another point is that cold weather is no hindrance to staying out, provided there is plenty of covering over the body, so that it does not feel chilled at any time. Plenty of woolen should be worn next to the body. Old-fashioned felt shoes make the best covering for the feet. At night the bed should be made up with a heavy blanket over the mattress. A blanket may be laid loosely between the sheets so that the body may be rolled in it. As to diet, Griffin does not believe in "stuffing" patients. Health is no more promoted, often, by forced than by moderate feeding, while the latter avoids the dangers of overloading the digestive powers. The giving of eggs has been overdone. Exercise must be carefully regulated. It is still a moot question whether pulmonary gymnastics shall be advised or not. Doubtless, where there is rapidly advancing disease, it is not well to prescribe deep breathing, especially if there is a pleurisy. Indeed, nature gives us the cue in many cases and by pain limits the respiration. In other cases, however, there can be no objection to moderately deep breathing, for by it the air of the lungs is better aerated, and certainly we cannot expect to get rid of diseased tissue in the presence of poor blood. It has been recently proven, also, that the secretion of the bronchial tubes is gotten rid of not so much by the action of the ciliated epithelium as by the pumplike action of the bronchial muscles.

Bilateral Torsion of the Fallopian Tubes.—M. Storer gives the history of one case, finding some sixty or more similar cases recorded since Bland Sutton first called attention to the condition in 1890. Torsion without strangulation is excessively rare. When it does occur, the symptoms are, as a rule, very alarming and are those of any acute internal arrest of circulation; sudden pain, almost always nausea and vomiting, faintness, complete arrest of bowels and often paralysis of the bladder, combined with local tenderness and increase in the size of the tumor from venous congestion. In the thirty-seven cases, however, in which the diagnosis before operation is stated, there was but one instance in which it is claimed that the exact condition was actually recognized. The correct diagnosis can probably be made only when it is known that a hydrosalpinx has been present previous to the advent of acute symptoms, and that that hydrosalpinx has undergone a rapid increase in size, especially if a previously pelvic tube has become abdominal. The causes of torsion are as yet but matters of theory. In a few cases the sudden stabbing pain has followed some muscular exertion. Certain conditions, such as a tubal tumor in the distal portion of the tube and its nonadherence, undoubtedly favor torsion. The tumor must be fairly high in the pelvis. The number of turns in the torsion varies from one-half a turn to five and a half turns. Torsion occurred thirty times on the right side, nineteen on the left, and was bilateral in four. The preference for the right side may be due to the anatomically greater play of the right mesosalpinx. The ovary is given as involved in eighteen cases, and not, in twenty-two. Apparently this complication increases the severity of symptoms. Immediate operation is the only treatment. Of the sixty-two cases enumerated, all but two recovered.

New York Medical Journal, March 10, 1906.

Balsam of Peru in Castor Oil as a Surgical Dressing.—E. V. Hubbard refers to the literature of this subject and declares that this combination of remedies deserves a greater popularity than it receives. He summarizes his personal experience in certain clinical cases, as felons, paronychia, deep burns, abscess, operation for tuberculous glands, etc. Iodoform in the balsam-oil mixture is disguised up to the strength of ten grains to the ounce. The balsam-oil proportions are half a dram of the former to one ounce of the latter. The dressing is valueless in eczematous affections and is no protection against erysipelas infection.

Diagnostic and Prognostic Value of an Examination of the Throat in Pulmonary Tuberculosis.—W. G. B. Harland notes that in many cases of pulmonary tuberculosis there are considerable wasting of the mucosa of the upper air tract and changes in the quality of the secretion, which becomes of a distinctly seromucous character. As a result, we have constantly recurring colds, post-nasal dropping, hoarseness, and cough. Such a combination of symptoms should

always lead to a rigid examination of the chest, observation of temperature, and bodily weight. The usual laryngeal changes in this disease are enumerated by the author, who considers it probable that the ordinary breath sounds are altered by the disease in the larynx, thus masking sometimes the local signs present in a diseased lung. As it is probable that macroscopic tuberculous lesions of the larynx do not ordinarily occur until after the general and local resisting powers have been partly destroyed, the appearance of laryngeal tuberculosis becomes, to a certain extent, an index of the seriousness of the patient's condition. The presence of any laryngeal involvements makes the prognosis less favorable, though not necessarily hopeless. Statistics have been collected to show that certain sorts of lesions portend less dangerous consequences than others, and that when certain parts of the larynx are affected the prognosis is more hopeful than when other parts are involved. Thus of those with simple infiltration twice as many improved as when deep ulceration was present, and of those without involvement of epiglottis or arytenoids three times as many improved as when these structures were involved. It is needless to say that difficulty in swallowing in tuberculous cases is always a most serious complication.

Diarrhea and Its Diagnostic Significance.—J. P. Tuttle says that the 101 varieties of diarrhea may all be classified under one of six types, viz., simple, serous, lienteric, toxic, mucopurulent, and reflex. The first variety is more a habit than a disease, and occurs in large eaters and drinkers, especially of beer and dry wines. The patients often have anal excoriations from repeated cleansing of the parts, occasionally hemorrhoids. Serous diarrhea generally results from severe nervous disturbance or exhaustion. It often occurs in the crises of acute diseases and occasionally as an intestinal crisis in tabes. It is at times vicarious, as in nephritis, and is often associated with relaxation of the sphincters. Lienteric diarrhea presents particles of undigested food in the passages. Analysis will show whether these particles are nitrogenous or carbohydrates; if the former, the trouble is doubtless in the stomach; if the latter, in the bowel. This variety may point to serious organic lesions. Toxic diarrhea results from the ingestion of infectious material, organic, inorganic or bacterial. It begins with nausea and vomiting, running into loose, fecal stools, later serous, and if protracted containing mucus and blood. Most of the foregoing are caused by cleansing the tract with oil or salines. Mucopurulent diarrhea is not, according to the author, a nemesis, but the expression of a hypertrophic cotant due to infection or autointoxication and may be due to ulcerations high up in the small bowel. Such cases demand instrumental examination. Reflex diarrhea may come from painful affections in any part of the body. Finally, we may have the diarrhea of impaction and that form which may come from the lodgment of a foreign body. The course to be followed in such cases is obvious.

Practical Results Accomplished with Radiant Energy.—Samuel Stern notes that the *x*-ray and high-frequency spark are of extreme value in the cure of all forms of epithelioma. They are of great value in the treatment of other malignant growths, in their ability to stop pain and prolong life, but should be used only in nonoperative cases, or in conjunction with surgical measures. In internal diseases they are of value in leukemia, Hodgkins' disease, various forms of chronic tuberculous conditions, in subacute or chronic rheumatism, lumbago, sciatica, or other forms of nerve affections. In skin diseases, the *x*-ray will show practically 100 per cent. cures in sycosis of the parasitic or nonparasitic type. Almost as great percentage in eczema of all varieties, and in psoriasis, but in the latter there is the usual chance of recurrence. In acne vulgaris, in conjunction with other treatment, it is of great value, but of not very much value in acne rosacea. It is very valuable in favus, trichophytosis, keloid, various forms of lichen, mycosis fungoides, folliculitis decalvans, and hypertrichosis. The *x*-ray, or the high-frequency spark, or the combination of both, is very valuable in the treatment of all forms of prurigenous affections due to any cause. The high-frequency spark accomplishes a great deal in the treatment of lupus erythematosus, lupus vulgaris, tuberculosis vera cutis, in the destruction of all forms of nævi, verrucæ, molluscum contagiosum, and other forms of superficial growths. It is of decided benefit in alopecia due to anemic condition of the scalp, and in alopecia areata.

American Medicine, March 17, 1906.

Without Mosqnitos There Can Be No Yellow Fever.—James Carroll argues that the logical conclusion from the investigations which have been made would seem to be that the parasite of yellow fever belongs to the animal kingdom for the following reasons: (1) It is absolutely necessary for its continued existence that it pass alternately through man and the mosquito, and its parasitic existence in these hosts is obligatory. (2) The fact that a period of about two weeks must elapse before the contaminated mosquito is capable of infecting, points to a definite cycle of development in that insect. (3) The limitation of its development cycle to mosquitos of a single genus and to a single vertebrate conforms to a natural zoologic law and does not agree with our present knowledge of the life history of bacteria. (4) The effects of climate and temperature upon *Stegomyia* and upon the rate of development of yellow fever parasite within the body of the insect are exactly the same as the effects of the same conditions upon the anopheles mosquito and the malarial parasite.

Gonorrhea in Women.—Palmer Findley says that anatomic recognition of gonorrhea of the urogenital tract may be impossible, particularly in cases of long standing. For this reason the diagnosis must occasionally rest upon the finding of an inflammatory lesion in one or more portions of the tract and associating these lesions with a history of exposure to gonorrheal infection. A diagnosis that admits of no doubt can only be based upon the finding of the gonococcus in the secretions or tissues. This is by no means easy in the chronic stages when there is little or no secretion, and the organism, which at best is recognized with difficulty in the tissues, is found in small numbers or may be wholly wanting. The small size of gonococci and their scarcity in the tissues of chronic cases may necessitate the microscopic examination of a large number of sections. This involves rare skill in technique, not only in the preparation of the sections but in the differentiation of the gonococcus from other cellular structures. Grave mistakes have been made in diagnosis by assuming that no infection exists because the usual complaints of an acute infection do not appear in the history. Since the cure of gonorrhea is so unsatisfactory, and when deeply seated is usually only accomplished by a mutilating operation which too often unsexes the woman, prophylaxis becomes the paramount issue in the management of gonorrhea of women. Unfortunately it is not alone the laity which is in need of education in this respect; the profession is often guilty of being too hasty in pronouncing a cure and in giving sanction to marriage and to the resumption of the marital relation. Untimely interference with uterine and urethral applications in the early stage of the disease too often causes an extension of the infection and makes a serious lesion of what might otherwise have been a self-limiting disease.

Actinomycosis Limited to the Urinary Tract.—E. MacD. Stanton records a case in which an actinomycotic lesion was limited to the kidney and bladder. The case was clinically one of cystitis and pyelonephritis, the actinomycotic character of the kidney lesions not being recognized during life or at the time of autopsy, but being discovered only upon histologic examination of the kidney and bladder.

Journal of the American Medical Association, March 17, 1906.

Some Possible Causes of Emaciation.—The points emphasized by R. C. Cabot are that cell growth, cell multiplication, and cell nutrition are profoundly influenced by age, by sexual influences, by internal secretions, by sleep and exercise, and by a multiplicity of hereditary individual and psychic factors not yet clearly distinguished. He first calls attention to the changes that take place with age, the gradual or fairly rapid loss of weight often observed as a part of the aging process in persons past middle life, which is often associated with arteriosclerosis, possibly as a result, possibly as a concomitant effect of some third unknown factor. With some exceptions, the rule is that during the years in which arteriosclerosis is prone to develop there is a loss of weight, usually gradual, sometimes rather alarming. The very rapid increase of weight often seen in growing children and after wasting diseases, is not the direct result of abundant food, but must be referred to a heightened energy of cell growth. The sexual influences are also factors in nutrition, as strongly suggested by the changes observed following parturition, the menopause, and castration of animals. The importance of internal secretions in maintaining or perverting nutrition is shown in the emaciation of Graves' disease, the increased weight in myxedema, and possibly by the local hypertrophies of Paget's disease and acromegaly. Lastly the possible decisive influence of sleep on weight is suggested by the rapid emaciation sometimes occurring in aneurism cases, when insomnia is produced by pain while the appetite remains excellent.

Autolysis.—P. A. Levene reviews the known facts in regard to tissue disintegration in the animal body. He shows that while proteid combustion in the normal organism is apparently different from the proteid disintegration of autolysis, the latter process does occur under normal conditions in the body. In health the autolytic disintegration is only such as is required to free the system from waste material and possibly to prepare its products for more rapid combustion. In conditions of defective nutrition, and in

certain conditions of disease, an exaggerated tendency to tissue self-destruction exists, and this is most remarked when the tissues are under the influence of protoplasmic poisons. In such cases, all the tissues are affected more or less, but there are conditions in which self-digestion of special organs takes place physiologically, as in the atrophy of the thymus or the involution of the puerperal uterus. The softening of tumors is also brought about by the same process. It has also been shown that autolysis may be one of the means resorted to by the organism to elaborate protective substances, such as antitoxins. Levene sums up the results of the study as follows: "Autolysis, then, is the process by which dead tissue is not only prevented from becoming a burden to the organism, but, in addition, becomes converted into useful fuel material. By the aid of these processes, diseased tissues, pathological formations, and new growths are removed and replaced by normal healthy tissues. The organism resorts to this process also for the elaboration of protective substances against bacteria and bacterial toxins. It still remains to be demonstrated whether or not in the course of autolysis enzymes are formed which are concerned in producing that energy which makes all animal functions possible."

Irrigation of the Abdominal Cavity.—J. W. Vaughan considers general abdominal irrigation after operations as absolutely contraindicated from a bacteriological point of view. A general peritonitis, understanding by this one involving all parts of the abdominal cavity, is, he thinks, an impossible condition unless brought about by some such method. We should try, he says, to aid nature in forming protective adhesions by the use of sterile gauze drains, following these as the exudate dries, by the glass tube, insuring free drainage. He believes that the disuse of irrigation in cases of typhoid perforation, as well as in appendicitis, would be followed by a marked reduction of the present mortality rate after these operations.

Alcohol in Carbolic Acid Poisoning.—After reviewing the history of the use of alcohol as an antidote to carbolic acid poisoning, T. W. Clarke and E. D. Brown report the results of a clinical and experimental study of the subject. The general conclusions from the experiments were: "(1) Alcohol has a local antidotal effect to carbolic acid burns, due to its solvent action. (2) There is no evidence of chemical antagonism between alcohol and phenol. (3) There is no effect produced by alcohol on carbolic acid poisoning after the latter has been absorbed into the system, as is shown by the intravenous experiments on dogs. (4) Alcohol and phenol placed in the stomach give no different results from phenol alone. (5) Lavage with alcohol is effective when the phenol is in the stomach, but its superiority over lavage with water is not pronounced." From the clinical aspect, alcohol seems to have a local antagonism to carbolic acid, and they would not say that it is of absolutely no value in poisoning by this drug. Its solvent action may nevertheless be, under certain conditions, a danger rather than an advantage, as shown by the more marked symptoms of intoxication seen when the poison has been taken in whiskey, and this seems to contraindicate the alcohol being used as an antidote and left in the stomach. The procedure recommended is as follows: Immediate abundant lavage with 10 per cent. alcohol, this to be followed by lavage with plain water, and stimulation as indicated. To be effective, alcohol must be used while the acid is in the stomach; it is of no use after it has been absorbed. The danger of pneumonia from inhalation of the regurgitated stomach contents during lavage in an unconscious subject is pointed out, and the authors advise during lavage turning the patient on the side or face, with the head low so that anything entering the pharynx will flow out through the mouth. Since using this plan they have had but few pulmonary complications in their patients.

Quinine in Pneumonia.—A. L. Custetter gives accounts of four cases of pneumonia treated with large doses of quinine as recommended by Galbraith, and says that he has had many others which he has treated in the same way with like good success. In Nogales, pneumonia is a very common disease, and under other methods of treatment a very fatal one. His mortality in pneumonia cases was formerly nearly 80 per cent., but since he has been using the quinine treatment according to Dr. Galbraith's method, he has not lost a patient. Out of a total of about thirty cases so treated, only one (one of those here reported) showed any signs of quinine poisoning (profound deafness and almost complete blindness), but in this case the symptoms passed off completely within ten or twelve hours, leaving no after-consequences.

A. S. v. Mansfelde calls attention to the recommendation of the use of large doses of quinine in croupous pneumonia, by Prof Theodore Juergenson in v. Ziemssen's "Cyclopedia of the Practice of Medicine," Vol. V, p. 165, and says that he has used just this treatment for the past thirty years. In this connection, he remarks that Dr. Galbraith's publication "demonstrates that nihilism in the use of individual drugs simply means lack of knowledge of their proper uses, with the consequent reliance on proprietary mixtures, which only too often are void of substance and consequently of action." Is it not a pity, he asks, that such masterly works as Ziemssen's Cyclopedia are so much ignored at the present day?

The Lancet, March 3, 1906.

Marked Intolerance of Belladonna.—T. R. Atkins' patient was a woman with cellulitis of the leg without abrasions, for whom forty minims of "glycerin and belladonna," representing twenty grains of the extract of the latter, were applied to the inner side of the foot. Within half an hour the patient complained of great swelling of the leg and a sensation as if the skin would burst. Dryness of the throat and lips, a feeling as if the nipples were being forcibly retracted, and difficulty of speech quickly followed. The patient now became delirious, the pupils were widely dilated and insensible to light, the hands were kept in perpetual motion groping for imaginary objects, and efforts were made to tear the bedclothes. This delirium lasted for some hours, after which she gradually became more composed but felt as if she had passed through a severe illness. In forty-eight hours the dryness of the throat and the pain in the breast had disappeared, though the pupils remained dilated and resumed their normal condition only on the fourth day. The treatment consisted in the administration of hot coffee and a quarter of a grain of morphine, together with the use of continuous hot applications.

The Psychology of the Tuberculous.—This question has been studied by A. S. Gubb, who notes that there are presumably two principal morbid processes at work in the determination of the psychical peculiarities noted in the tuberculous: (1) changes in mental temperament, presumably due to the action on the nervous system of the toxins of the tubercle bacillus, and (2) modifications in character due to mechanical interference with the cerebral function, secondary to the deposits of tubercle within, or upon the brain. Such deposits may cause cerebral impairment, and even epilepsy or melancholia. The characteristic features of the general psychology of this class of patents are instability, feverish activity alternating with intense depression, phases of despair with intervening elaboration of plans for the future, hypochondria—from which the patient may seek relief in intense application to his work or by reckless indulgence in sexual pleasures. There is a tendency to sentimentality and generalization, that is, in general, a marked intensification of cerebral function, the manifestations in a given case varying according to the temperamental peculiarities of the individual patient. The author notes that the reproductive functions are peculiarly active, while the fertility of tuberculous couples is almost proverbial. The feverish activity of such people is often regarded as the cause, while in reality it is the result of the disease. All these features are notable in cases with a short, acute terminal period. Up to a certain point the exaggerated metabolism appears to supply the necessary amount of nervous energy until the final breakdown comes on and the weakened system succumbs to the tuberculous invasion. Two interesting clinical histories are given by the author, both in the same family; in both an initial local pulmonary lesion was followed by a marked deterioration in the moral status. Post-mortem examination in one revealed old tuberculous meningitis and fresh tubercles at the base, the initial lesion having been a tuberculous pleurisy with invasion of the adjacent lung.

The Diagnosis and Treatment of Tuberculous Pleurisy.—According to Sidney Martin, the diagnosis requires a consideration of the following factors: (1) Mode of onset; (*a*) insidious, with fever, but no chest signs or symptoms; then, in a week or two, we find well-marked signs of pleural effusion. Unilateral deficiency of chest movement is of especial significance. (*b*) The history of a similar attack of pleurisy a few weeks or even months earlier—on the same side (usual) or on the other side. (2) Course of the disease, including examination of the effused fluid. Non-tuberculous effusions (excluding empyema) tend to disappear. In tuberculous cases, the course is longer in its acute stage, slower in recovery, and there is a tendency to chest deformity with lung contraction. Effusion does not always occur; instead, there may be an increasing thickening or fibrosis of the pleura, with a prolonged pyrexia Recovery may occur under the latter conditions, or one may have a subacute general tuberculosis or the chronic pulmonary disease. The fluid removed in cases of tuberculous pleural effusion sometimes coagulates spontaneously; if, however, the disease has lasted some time or has become chronic, coagulation may be slight or absent. In some cases much may be learned by an examination of the fluid. The author does not claim that the effusion in a tuberculous case never contains the bacteria which are the cause of non-

tuberculous primary pleurisy, but if these and other bacteria are shown to be absent by cultures made from the centrifugalized deposit (100 c.c.)—*i.e.* if the fluid is found to be sterile by cultivation on ordinary media—the disease is tuberculous. In some cases microscopical examination and inoculation of the deposit of the centrifugalized fluid are important. Positive results sometimes follow here, even when we are unable to discover the bacilli in the effusion. As to treatment, the author declares that in the acute stage, beyond the ordinary measures of rest in bed and good nursing, the main point that will arise for decision is the question of removing the fluid from the chest. There does not appear to be any greater danger in removing the fluid in tuberculous cases than in the non-tuberculous, and, indeed, there may be a definite reason in advising the removal of the fluid, owing to the permanent adhesions that are liable to be formed in tuberculous cases. Apart, therefore, from any urgency for paracentesis such as may occur when there is respiratory distress, it is not wise to allow a large quantity of fluid to remain in the chest for too long a time. If the fluid, therefore, is large in quantity and shows no sign of absorption, it had better be removed. Cases which run a prolonged course with pyrexia, and perhaps no urgent symptoms, are best treated by living in the open air, properly wrapped up and well fed. After the pyrexia has ceased all such patients require a prolonged course of treatment in the open air, in order to help the healing of the tuberculous lesion. If this were done more systematically it would, perhaps, to a great extent prevent a second attack of tuberculosis which so frequently affects the lung tissue and leads to either a very chronic illness or more immediately to death.

British Medical Journal, March 3, 1906.

A Rapid Cure for Lumbago.—J. Farquhar commends the use of the Ung. Antimoni tartrat. (B. P.) in the treatment of lumbago. It is to be well rubbed in. He finds that Croton oil liniment used in a similar way is efficacious in cases of chronic sciatica and allied disorders in the hip region. The pain may return after a time, but the remedy is very useful in relieving the stiffness and gnawing attacks characteristic of this class of disorders.

A Case of Myxedema.—The report is made by T. Fraser, whose patient was a man of 42 years. Typical symptoms were presented, while the less conspicuous manifestations, such as slow heart action and respiration, sluggish mentality, lowered temperature, and recurring cramps were also in evidence. The illness covered a period of eight years. Speedy improvement took place, all the symptoms disappearing after a few weeks' course of thyroid extract, and the weight diminishing some forty pounds. The patient has been taking thyroid regularly for some years and has maintained a nearly normal health standard. At one time, when he was deprived of the remedy for two weeks, several of his original symptoms reappeared—such as feelings of coldness, husky and slow speech, and face swelling, but all disappeared in the resumption of the remedy.

The Treatment of Neurasthenia.—The first and most obvious indication, according to G. Rankin, is the enforcement of rest, preferably away from the patient's relatives and usual home surroundings. Absolute rest may give place after a while to a drive or walking. Light literature may be allowed, or the pursuit of any simple hobby or pastime. The muscular system should be improved by massage and faradism. Much depends on the daily visit of the medical attendant. An antiseptic mouth wash should be given, and any error in digestion remedied. The bowels must be regularly evacuated, while the diet must be carefully adjusted to the patient's digestive power; at first it may consist of milk foods, thin soups, fish, fowl, and game. Red meat should be given only once daily, tea should be avoided, all vegetables and fruit should be cooked, bread stale or toasted, fats in abundance, and at least a quart of milk daily. Cod-liver oil may be added to the daily dietary, beginning with very small doses. Stout, Burgundy, or claret may be used with luncheon. For insomnia we may give coal tar products, or even small hypodermics of morphine. If anemic, the patient should receive iron; but it is useless to begin it until the digestion is regulated. If the iron disagrees, we may give some form of manganese, phenacetin with caffeine for headaches, the Paquelin cautery for special tenderness, bicarbonate lavage for gastric cleansing, and a change of surroundings for a few weeks before resuming work, all serve as adjuncts. A most careful hygiene and regularity of living must follow. A fixed portion of the day should be spent in the open air, while every slight ailment calls for immediate attention, so that the risk of incurring nervous exhaustion may be reduced to a minimum.

The Pathology of Epilepsy.—As a result of personal investigations J. Turner summarizes the following changes occurring in epilepsy. Most important are those in the nerve cells. These may show (1) a form indicative of imperfect development; (2) retention of subcortical nerve cells; also an indication of imperfect development; (3) either an acute form of cell change, similar to that produced by ligature of the cerebral arteries in a dog, or (4) groups of darkly-stained, shrunken cells, representing a more chronic change, and very probably, at all events in some cases, the sequel of that just described. On the part of the vascular system we may find (1) large numbers of blood plates in the blood; (2) different forms of intravascular clotting, probably in large measure derived from amalgamation of the blood plates, but to some extent also probably due to destruction of red blood corpuscles; (3) small cortical hemorrhages, which in some cases can be traced to rupture of a vessel blocked up by the aforementioned clot. He submits the proposition that this correlation of defectively-developed, and probably unstable nerve cells with the local stasis of the blood current resulting from intravascular clotting, constitutes the pathological basis of the typical epileptic seizure.

Münchener medizinische Wochenschrift, February 27, 1906.

Lymphangiectomia Auriculi.—Vörner says that it has heretofore always been taken for granted that when clear fluid was obtained on incising an othematoma the colorless nature of the fluid was due to degeneration or disappearance of blood pigment in what was originally a pure hematoma. Various observers have claimed that collections of lymph might also be formed under similar conditions, but the former view has always prevailed. He describes a case in which a fluctuating swelling 2.5 cm. in diameter appeared spontaneously at the upper border of the ear of a man twenty-two years old. Although the skin over the mass was of a slightly bluish shade, on making an incision with the galvanocautery, in order to avoid contaminating the contents with blood, only clear yellowish fluid was obtained. Various tests on the fluid indicated that it was lymph. Its centrifuged sediment contained no red corpuscles but only a few lymphocytes and endothelial cells, and the wall of the cavity on histological examination was found to be lined, partially at least, with endothelial cells, so that the author concludes that in some cases lymphangiectases of the ear may resemble othematomata.

Isolated Subcutaneous Fissures of the Long Bones.—Giese says that all injuries about the limbs which give rise to subjective symptoms which appear to be disproportionately severe in comparison with the objective findings, should be subjected to *x*-ray examination. While the occurrence of fissures of the long bones has frequently been described in connection with more severe injuries, it is not generally recognized that such lesions may be produced under conditions that give rise to only comparatively slight objective evidence. It is only since the introduction of the *x*-ray that it has been possible correctly to diagnose such cases. He describes a case in point, the patient being a boy of eleven years, who after a fall which appeared to result in only a superficial bruise, complained of great pain and inability to walk. Examination with the fluoroscope revealed nothing abnormal, nor did a radiograph taken from the front. Another view showing the median aspect of the bone revealed a fine tissue of considerable extent, however. Another diagnostic point mentioned by the author is the fact that in the present instance the hemorrhage was manifestly subperiosteal, so that the suspicion of a bone injury seemed justified.

Fatal Benzin Poisoning and Its Postmortem Appearances.—Burgl describes a case of fatal poisoning with this agent, the patient being an infant of eighteen months that received 30 or 40 grams of benzin. Death followed in coma at the end of about three and one-half hours. The autopsy findings are described in great detail and presented evidences of death by suffocation, combined with more or less pronounced symptoms of carbonic oxide poisoning. The most characteristic lesions are said to be extensive hemorrhages, which appear on the surface of the lungs and also throughout their substance. An inflammatory condition of the lymphatic apparatus of the digestive tract was also noticed. The general manifestations comprised cyanosis, dilated pupils, fluidity of the blood, congestion of the lungs, the trachea, and bronchi; the air passages were filled with bloody foam, and there was congestion of the brain, liver, and kidneys. In this case, as in the three others that have been described in the literature, the symptoms during life included rapid loss of consciousness, dilated pupils, cyanosis, rapid, small pulse, cold skin, rapid and superficial breathing, and convulsions.

Diarrhea.—Creel employs the following if Squibbs' cholera mixture is complained of as being "too hot":

Book Reviews.

An Atlas of Human Anatomy for Students and Physicians. By Carl Toldt, M.D., Professor of Anatomy in the University of Vienna, assisted by Professor Alois Dalla Rosa, M.D. Translated from the Third German Edition and Adapted to English and American and International Terminology by M. Eden Paul, M.D., Brus., M.R.C.S., L.R.C.P. Sixth Section: G, Neurology; H, The Organs of the Senses (Figures 1124 to 1505 and Index). London: Rebman Limited; New York: Rebman Company, 1904.

This sixth and final volume of Toldt's admirable Atlas is perhaps the most important, certainly the most interesting, of the series, dealing, as it does, with the anatomy of the nervous system and the organs of special sense. In notices of the earlier volumes we have described the general character and scope of the work, and have expressed our appreciation of its excellence. It is purely an atlas, without descriptive text, and cannot take the place of Cunningham or Gerrish or Gray as a text-book for the student's use; but as complementary to any of these treatises it cannot be too highly commended. No part of the anatomy of the human body, gross or microscopical, is slighted; some of the regions depicted are, indeed, to be found in no other anatomical treatises with which we are familiar, and can be seen by the student only in special and skillful dissections. The translator has added a few useful explanatory notes, and a very complete index concludes the volume. The work as a whole is a most welcome addition to anatomical literature—if a series of pictures can be so designated—and as a reference atlas for the surgeon or internist it has no equal.

A Treatise on Diseases of the Skin. For the use of advanced Students and Practitioners. By Henry W. Stelwagon, M.D., Ph.D., Professor of Dermatology, Jefferson Medical College, Philadelphia; and Clinical Professor of Dermatology, Woman's Medical College, Philadelphia. Fourth Edition, Revised. Philadelphia and London: W. B. Saunders & Company, 1905.

The first edition of this work appeared in June, 1902, and the fourth edition in October, 1905. This is a sufficient indication of what the profession thinks of the work, and relieves the reviewer of any necessity for praise. In the present edition the principal additions are to be found in the section treating of the *x*-rays, Finsen light, and d'Arsonval (misprinted d'Arsonoal) current as therapeutic measures. The paragraph treating of the latter might, we think, have been considerably amplified with advantage, for though, as the author states, the use of the higher-frequency current is still in the experimental stage, it has given some positive results and is deserving of more than the few lines accorded to it by Dr. Stelwagon. One decided improvement is the substitution of several illustrations taken from the author's own cases for those borrowed from Mracek's Handatlas in the earlier editions. The work is well illustrated with 32 colored and halftone plates, and some 250 pictures in the text. The dermatological specialist, as well as the general practitioner who needs to inform himself regarding the most common diseases of the skin, will find this work most helpful.

The Surgical Treatment of Chronic Suppuration of the Middle Ear and Mastoid. By Seymour Oppenheimer, M.D., Otologist and Laryngologist to Gouverneur Hospital; Otologist and Laryngologist to Mount Sinai Hospital Dispensary; Fellow of the American Laryngological, Rhinological, and Otological Society. Philadelphia: P. Blakiston's Son & Co., 1906.

The treatment of mastoid disease is one of the recent developments of medicine which has been productive of untold saving of life, and it is a field which is being tilled boldly by many. Most of the work hitherto accomplished in this line has been recorded only in periodical literature, and the writer of this treatise has done well to collect in permanent form the results of the labors of the multitude of otologists who have been working along these life-saving lines. The work is, however, in no sense a compilation, but a thoroughly original treatise, in which the views of the writer are expreseed in no uncertain manner. The reader is impressed with the feeling that he is under the personal guidance of an expert; if he is a specialist, he may not always accept the views of the author, but he must respect them; if he is a general practitioner, who must perforce be a specialist in all branches of medicine, he can have no safer guide in this particular field. Dr. Oppenheimer is a lucid writer of good English, which some original investigators are not, unfortunately, and the reader of his book has no difficulty in following him through every point of his argument and in the description of operative details. The illustrations are deserving of special praise. There are forty-six halftone plates made after special dissections, and many of them are supplemented by diagrammatic plates, facing the halftones, which serve as keys in explanation of the original plates. The work deals not alone with the treatment of mastoid and middle-ear disease, but presents an exposition of the symptomatology upon which the diagnosis is based. It is a treatise which no specialist can do without, and which the general practitioner—not only the one who must treat his own cases, in whatever special lines they may fall, but also the more fortunate city physician, who can command the assistance of the special surgeon when he has made his diagnosis—will find of the greatest assistance in cases of neural disease accurring in his daily practise.

Pathogenic Microorganisms, including Bacteria and Protozoa. For Students and Practitioners of Medicine and Surgery and Health Officers. By William Hallock Park, M.D., Professor of Bacteriology and Hygiene in the University and Bellevue Hospital Medical College and Director of the Research Laboratory of the Department of Health, New York, assisted by Anna W. Williams, M.D., Assistant Director of the Research Laboratory. New (second) Edition, Enlarged and Thoroughly Revised. Philadelphia and New York: Lea Brothers & Co., 1905.

In the five years that have elapsed since the first edition of this work appeared, progress in the domain of human microparasitology has been rapid. Especial importance has been assumed by the protozoan parasites, which are found to be the pathogenic agents in an increasing number of diseases. The majority of tropical diseases appear to be due to the presence of animal microparasites, and the belief is growing that most, if not all, of the exanthemata, including syphilis, have an animal causation. The author has recognized this fact and has included in this edition of his work a considerable section, which we predict will be yet more extensive in future editions, to a consideration of the protozoa. The chapters dealing with the bacterial parasites have been thoroughly revised, so that the book in its present form may be said to reflect the latest knowledge in the entire domain of microparasitology. It is not intended for specialists, but can be confidently recommended to students and practitioners of medicine who would be informed regarding the causation of infectious diseases.

Military Hygiene. By Robert Caldwell, F.R.C.S., D.P.H., Lieutenant-Colonel Royal Army Medical Corps; formerly Medical Officer in Charge District Laboratory, Meerit; Member of Committee on Field Sanitation in Connection with Surgeon-General's Report on South African Campaign; Medical Officer in Charge, District Laboratory and Isolation Hospital, First Army Corps. New York: William Wood & Company, 1905.

This is an interesting book of about 400 pages, and worth careful reading by every medical officer of the military and naval services. It appears to be rather a series of essays on the various subjects treated than a text-book, and lacks so much in the way of amplification and detail as to render it scarcely sufficient as the only guide to the military sanitary officer. That it should be the latter is evidently not the purpose of the author, who has apparently only modified his recent prize essay on "The Prevention of Disease in Armies," to render the information therein more accessible. The book is largely based on the personal experiences of the author, and contains much valuable information relative to the sanitary history of the recent Anglo-Boer War which had previously not been available. It is the latter part especially which gives the book particular value to the medical officer and epidemiologist. One defect to be noted is the apparent slight effort made to review recent literature bearing on medicomilitary sanitation and further broaden the author's experience by the combined experience of many others. The author is a strong believer in the apparent *de novo* origin of disease from previously latent and apparently innocent germs assuming a virulent character, and cites many interesting examples to prove this important point. It is noticeable that he classes "jaundice" as a separate disease among the affections to which the soldier is liable, and also classes "sewer gas" as one of the direct agents inducing Malta fever and other diseases. The book is naturally prepared more especially to meet the needs of the British army surgeon and certain chapters have no great value for medical officers of other services. On the whole, all such others should read it, but few need to study it. The book is well gotten up and entertainingly written. Even if incomplete as a text-book, it is a valuable contribution to sanitary literature.

A Study in Nursing. By Miss A. L. Pringle, Formerly Matron of St. Thomas' Hospital, Superintendent of the Nightingale Training School for Nurses, Superintendent of the Nurses at Edinburgh Royal Infirmary. London and New York: The Macmillan Company, 1905.

In this little book a veteran nurse writes most pleasingly about many things in connection with her profession. Every page bears ample witness to a wide experience and a thorough knowledge of human nature. The high ideals of nursing, as well as its humble details, are constantly kept in view. The book is well worthy the attention of all nurses.

Society Reports.

THE MEDICAL ASSOCIATION OF THE GREATER CITY OF NEW YORK.

Stated Meeting, February 12, 1906.

THE PRESIDENT, DR. THOMAS E. SATTERTHWAITE, IN THE CHAIR.

Filtration of Public Water Supplies.—By MAJOR CASSIUS E. GILLETTE, Engineer Corps, U. S. A. (See page 468.)

Public Water Purification in Massachusetts.—By Dr. CHARLES HARRINGTON, secretary of the Massachusetts State Board of Health. (See page 472).

On the Problems of the Public Water Supply of New York City.—ERNST J. LEDERLE, Ph.D., a member of the State Water Supply Commission, discussed this phase of the subject. He stated that the questions of adequate transportation facilities and the proper housing of its school children, the furnishing of an abundant supply of water, were three matters of most vital importance which the city was always behind in. For the past five or six years competent authorities had stated that within a very short time the water supply of the city of New York would be insufficient for its wants, and for the increase in population and the increase in the use of water. Various commissions had been appointed during the past five years to investigate this subject, and as the result of their labors, a number of very excellent and exhaustive reports thereon had been submitted, and in all of these the importance and urgency of an additional water supply were emphasized. As a result of this agitation, two bills bearing upon the subject were passed by the Legislature in 1905. One of them, known as the McClellan Bill, authorized the Mayor of the City of New York to appoint a board of water supply, the duty of which should be to proceed immediately and with all reasonable speed to ascertain what sources existed and were most available, desirable, and best for an additional supply of pure and wholesome water for the city of New York. This board was thereupon appointed, and based upon its labors and investigations, and aided by the reports submitted by previous commissions, a report was compiled and submitted to the Board of Estimate and Apportionment of the city of New York on October 9, 1905, in which the need of an additional water supply was again emphasized, and a certain section of the State recommended in which to obtain that additional supply. The plan submitted by this board entailed the enormous expenditure of over $161,000,000, and a great deal of public opposition to it had developed, including many formal protests which would eventually be taken up by the State Water Supply Commission. This latter commission would have to decide, first, whether the improvement asked for was a public necessity; second, whether the plans, as outlined, were just and equitable to those affected by it, and whether it affected the present or future water supply of the section recommended; third, whether the city of New York had made proper provision for the payment of direct and indirect damages to the property-holders.

The sources for an additional water supply recommended by the board in its report of October 9, 1905, were the following: 1. Esopus creek, to be taken at a point near Olive Bridge. 2. Rondout creek, to be taken at a point near Napanoch, together with three small streams tributary to the Rondout. 3. Schoharie creek, to be taken at a point near Prattsville. 4. Catskill creek, to be taken at a point about one mile north of East Durham, together with several tributary streams. The estimated yield of these proposed sources would aggregate 660,000,000 gallons daily. The conclusions offered by the Board of Water Supply were as follows: 1. The Catskill Mountain watersheds were the most available, the best, and the cheapest from which to obtain a proper additional supply of water for the city of New York. 2. The order of development of these sources should be Esopus, Rondout, Schoharie, and Catskill. 3. The Borough of Brooklyn should look for immediate relief from the water famine conditions existing to the water collected and stored in the sands of Long Island, and should use every effort to make these sources available. 4. To insure an addition at the earliest possible time of some 80 to 150 million gallons per day to the safe available Croton supply, work should be concentrated on the location and construction of the aqueduct from the Croton watershed to Ashokan reservoir, and the construction of the latter.

In connection with his remarks, Dr. Lederle showed a number of interesting lantern slides of views of the present Croton watershed, illustrating the improvements that had been made there in recent years from a sanitary standpoint. In reply to the claim made by some that the Hudson River offered the most available source for an additional water supply, Dr. Lederle said that one objection to that plan was that the water would have to be pumped, and another was that if 500,000,000 gallons of water were taken from the Hudson River daily at a point say as far up as Hyde Park, which was above the influence of salt water, it would necessitate the building of compensatory reservoirs in the Adirondacks, to maintain the normal flow of the Hudson river.

The Relation of Sewage to the Public Health.—Dr. HERBERT E. SMITH, dean of the Faculty of Medicine, Yale University, presented this paper, in which he briefly discussed the salient points of the dangers of sewage to the public health, and the means by which the infectious organisms might be transmitted from sewage to the food of man. Air transmission was properly regarded as of less importance than formerly. The air of sewers had been found to be surprisingly free from bacteria of any kind, a condition easily accounted for by the difficulty with which bacteria passed from a fluid to a gaseous medium, and by the facility with which they were removed from the air on coming in contact with wet surfaces. It had to be conceded, however, that infectious sewage organisms might be transmitted through the air from dried and comminuted sewage of any sort. In speaking of the fly as a disseminator of infectious organisms, Dr. Smith called attention to the coincidence between the occurrence of typhoid fever in the country districts in the summer and early autumn and the great abundance of flies in those seasons. He ventured to predict that when this method of transmission had received more careful consideration, the fly would be found to rival the historic well as a means of disseminating typhoid fever. The facts of the water transmission of infectious organisms were well known, and great epidemics of typhoid and cholera had been traced to this method of dissemination. The danger from infection through the medium of ice formed from contaminated waters seemed to have been overestimated, as clear ice was commonly of very low bacterial content as compared with the water from which it was formed. Another fortunate feature was that a freezing temperature was unfavorable to pathogenic bacteria, and as ice was commonly stored some months before it was used, this tended to diminish the number, and to lessen their virulence. So potent were these modifying conditions that, although ice was frequently cut from sources that would not be tolerated as sources of drinking water, there were almost no authentic cases of infection through the use of ice. The transmission of infection by the agency of milk was closely connected with contaminated water, through easily understood relations. There were cases on record where milk infection had been traced to the agency of flies. Of other means of transmission green vegetables were a possibility, and should be considered where it was proposed to use sewage for irrigation and the fertilization of truck farms. The remaining means most in the public mind was that through the agency of shell-fish. This was a real danger, as indicated by a number of demonstrated epidemics, and by numerous probable isolated cases, as well as by the known conditions of oyster culture.

Ultimate Disposal of Sewage.—George A. Soper, Ph.D., a member of the New York Bay Pollution Commission, said that the problem of the disposal of sewage was one that had arisen as a result of the concentration of population. In the beginning there was very little difficulty, apparently, for man to dispose of his wastes in a manner that would meet with the most exacting demands of the modern hygienist. He simply disposed of his wastes wherever it happened to be most convenient to him, and then moved away. That could not be done now in the cities and towns; there it was necessary to move the wastes away, and it gradually had become necessary to move them further and further away, in order to guard against, first, the production of offensive odors, and, second, the production of disease.

Originally, sewers were not built to carry off what we now call sewage, but were designed as underground drains for the purpose of carrying off rainwater chiefly. Both in London and Paris they were built for that purpose, and as late as 1815 it was made a penal offense in London to use the underground drains for any other purpose than to carry away the storm water and slops, and it was not until 1847 that cesspools and privies were abolished and the underground drains were utilized for the purpose of disposing of sewage. The statute books of many of the States of this country contained laws pertaining to the disposal of sewage; in some this control was only partial; in others it was more or less stringent, while in comparatively few the restrictions were very severe. Among the latter were New York, Massachusetts, Connecticut, Vermont, New Hampshire, and Wisconsin. In New York State all projects relating to the disposal of sewage had to be submitted to the State Commissioner of Health for his approval, and the emptying of unpurified sewage into any of the waterways of the State without a permit was prohibited. The laws themselves were efficient, but difficulty lay in their proper enforcement.

Dr. Soper said that the employment of sewage purification processes was a comparatively new development in sanitation. In this country twenty-three of the States had plants for that purpose a year or so ago. Of the total urban population of about 28,000,000, 73 per cent. emptied their sewage into inland waterways and 23 per cent. emptied theirs into the ocean, leaving about 4 per cent. that purified their sewage. The total amount of solid matter in sewage, roughly considered, should range from 150 to 400 grams per person per day. About one-half of this was organic matter, and about one-third was suspended in the form of solids in the water. These figures were mere approximations, but they served very well to give a general idea. It had often been supposed that the fertilizing ingredients in sewage could be employed to advantage, and many projects toward this end had been arranged. Unfortunately, the hope of running sewage disposal works with profit to be realized from the sale of the fertilizing materials recovered had always met with disappointment. The dilution of the manure was far too great and the methods of extracting the useful properties were too expensive to make such projects profitable. The inoffensive disposal of sewage was always an expensive undertaking, and experience showed that it could never be undertaken except at a considerable net annual outlay. Carefully managed sewage farms sometimes brought in a small partial return, but in this case the chief value of the sewage lay less in its fertilizing than in its irrigating properties.

The chief method of disposing of sewage at the present time was by dilution. It was emptied into the nearest waterway, and, if the supply of water was sufficient, it naturally purified the sewage in time. The question arose, how much sewage could be emptied into a watercourse without overcharging it? It had been found that for such rivers as we had in New England, a dilution of about one part in twenty-three was usually sufficient to avoid the production of odors. The dilution in salt water, however, was not so favorable, as salt water would not digest as much sewage as fresh water. Extensive nuisances had occurred in many tidal harbors through the emptying of sewage into the water without purifying it or insuring its dilution by adequate currents.

In disposing of sewage it was not always necessary to use the most efficient process, for the reason that it was not always necessary to attempt to secure the same degree of purification. Partial purification was often sufficient, as, for example, when the sewage was to be emptied into a small stream which had some, if limited, capacity for digesting it. In the ultimate disposal of sewage the fate of the bacteria always played a leading part. Among the oldest methods of sewage disposal was that of the sewage farm, such as had been in existence in Paris for thirty-five years. The sewage of Berlin was also purified in sewage farms containing about 13,000 acres. The method was extravagant in this respect, that a very large amount of land was required, one acre sometimes being necessary to dispose of the sewage of about 350 people. In certain sections of this country, chiefly through the efforts and experiments of the Massachusetts State Board of Health, one of the most efficient methods of sewage purification had been introduced, namely, the intermittent filtration method. By this method the sewage flowed upon a specially constructed bed of sand which, in operation, was alternately saturated and drained, or rested. By this filtration process nearly all of the bacteria were removed from sewage. Unfortunately, this method required large beds of a suitable sand which was not always readily obtainable.

Recently much more rapid methods of sewage purification had been devised. Among the best of these was the method requiring the use of contact beds. The beds were especially constructed of gravel, ranging in size from particles about as large as a pea to others about the size of a small apple. The beds were often eight feet deep. Under favorable conditions they were capable of removing about 90 per cent. of the bacteria and 75 per cent. of the suspended organic matters in sewage. Contact beds were operated by allowing the sewage to flow into them from the bottom, whence it rose to the top, rested for some time, and was then drawn off, the whole process lasting about six hours. A preliminary treatment for the removal of the coarser particles in the sewage was necessary. The city of Manchester disposed of 150,000,000 gallons of sewage per day in this manner. One of the most promising methods of purifying sewage was by means of percolating or sprinkling filters. These were gravel beds composed of particles two to three times as large as those employed in contact beds. The sewage to be purified was sprinkled on the surface and allowed to percolate, or drip through to the bottom. Filters of this type were capable of removing 80 to 90 per cent. of the bacteria and a large proportion of the suspended solids. The effluent was non-putrescible. Sprinkling filters, when properly built and operated, were capable of purifying over 2,000,000 gallons of sewage per acre per day. They required some preliminary process to remove the coarser solids.

One of the simplest of the so-called preliminary processes was screening. Screens were built in many ways and of different sizes, according to the work which they were intended to perform. Many of them were extremely ingenious and efficient. Another preliminary process was sedimentation, in which the sewage was allowed to move slowly, or come to a complete rest, in tanks, during which many of the solid matters were deposited. The most promising and efficient preliminary method employed the so-salled septic action of bacteria to turn into liquids and gases many of the decomposable solids in sewage. Septic tanks were practically sedimentation basins in which the sewage was stored for eight hours or more. Under favorable conditions the total organic matter in sewage could be reduced about one-third and the bacteria about 60 per cent. by septic tanks. The sewage, thus partially purified, was

then suitable for final treatment upon sprinkling filters or contact beds.

It had often been supposed that the use of chemicals could be employed to advantage to purify sewage, but they were now most extensively employed to aid the precipitation of the solid matters to form sludge. The disposal of this sludge was a serious matter. The county of London treated about 230,000,000 gallons of sewage in this way and had several large steamers to carry the resulting sewage sludge out to sea where it was dumped. There were probably not far from 200 sewage disposal plants in Europe operated upon this principle. New York city had several in the suburbs. The method was not capable of removing a high percentage of the bacteria and suspended matter. Only about 80 to 90 per cent. of the bacteria disappeared and the effluent was usually putrescible.

The Commercial Value of Clean Water.—Mr. George C. Whipple, C.E., read this paper. He stated that there was one phase of the subject of water filtration that had not yet received the attention it deserved, namely, the commercial value of clean water. We might start with the general axiomatic propositions that unpolluted water was worth more than polluted water; that soft water was worth more than hard water, and that clear, colorless, good-tasting water was worth more than one that was high-colored, turbid, or ill-smelling. As a basis of arriving at the depreciation which it was fair to deduct from the value of a water supply to a community because of its contamination, we might use the value of human life as determined by court decisions, the death rates from typhoid fever, and other water-borne diseases, as far as we knew them, the morbidity of these diseases, their duration, the loss of wages, cost of medical attendance, etc. A critical study of these data for a number of American cities had shown that for every death from typhoid fever the vital assets of the community were reduced in value by at least $10,000; and that for every unit death rate per 100,000 chargeable to water-borne typhoid fever it was fair to deduct a depreciation of $2.75 per million gallons from the value of the public supply, assuming a water consumption of one hundred gallons per capita daily. This was equivalent to ten cents per capita per year for each unit death rate from typhoid fever per 100,000. Thus, in Albany, filtration reduced the annual typhoid death rate from 104 to 26 per 100,000, thereby rendering each person of the community potentially richer by an income of $7.80 a year. Mr. Whipple then discussed, from a commercial standpoint, the depreciation of value due to drinking water that had unpleasant esthetic characteristics, such as taste, turbidity, or color; also, from the same standpoint, the advantage of soft water over hard water, and of cool water over lukewarm water, such as was usually obtained from surface reservoirs in this climate in the summer. He showed that clean water had a distinct commercial value, and that filtration paid even when its object was simply to make a turbid water clean, or a colored water colorless. In Watertown, N. Y., the elimination of color from the Black River supply had increased the value of the water by $12.40 per million gallons; in Philadelphia, the removal of the mud in the Schuylkill river water had increased its value $20 per million gallons; if the odor of the Ludlow water in Springfield could be removed its value would be materially increased. In Oberlin, Ohio, the softening process had saved the people $12 for each million gallons delivered; in Winnipeg, Manitoba, $39 per million gallons. The speaker said he confidently believed that many would live to see the day when filtration would be not only demanded by the public, but when our health laws would require that every surface water used for domestic supply should be submitted to some form of artificial purification. To bring about this much-desired situation the medical profession could do much, and, in justice to the teachings of modern sanitary science, it should lend its powerful influence to this movement.

AMERICAN LARYNGOLOGICAL, RHINOLOGICAL, AND OTOLOGICAL SOCIETY.

Meeting of the Middle Section, Held in Chicago, February 24, 1906.

Dr. Wm. J. Ballenger in the Chair.

Bullet Wound of the Mastoid.—Dr. James E. Logan of Kansas City, Mo., reported the case of a man, forty-eight years of age, who was shot in the right ear on Christmas Day, 1896. The bullet, 38-caliber, first passed through the fleshy portion of the right shoulder and entered the external meatus, lodging in the middle floor of the ear. Facial paralysis on the right side immediately followed. An operation was performed at once for the removal of the bullet, but without success. The middle ear began to suppurate while the patient was still in the hospital. The discharge stopped after a month or six weeks had elapsed. These attacks of suppuration occurred at intervals, followed by periods of cessation, until 1902, after which time the suppurative process continued without interruption. Pain was very severe at times in the region of the ear and on the top of the head, but there were no other symptoms referable to the head except the constant facial paralysis. The man was operated upon by Dr. Bisby, July 6, 1905, who was unable to locate the bullet. The suppurative process continued with increasing activity, and patient was sent to the author December 11, 1905. Patient's condition now was that there was very little pain; temperature was 99.2°, pulse 80, tongue coated. The tissues covering the mastoid and extending over the occiput were highly inflamed, and a fistulous opening existed beneath the lobe of the ear, allowing some of the discharge to pass through this channel. Much necrosis was evident, which accounted for the terrible odor emitted from the wound. On September 18 an operation was performed, all necrosed bone which could be found being removed. The patient made a rapid and uneventful recovery.

Anesthesia in Tonsil and Adenoid Operations.—Dr. L. C. Cline of Indianapolis, Ind., suggested the following points for discussion: (1) Is it necessary to use a general anesthetic in all or in the majority of operations for the removal of adenoids and tonsils? (2) If so, what is to be the choice of an anesthetic? (3) Cannot these operations be done just as efficiently, with less shock and danger to life and postoperative complications, without a general anesthetic? The author believed that in the majority of cases it was possible to do as clean and as thorough an operation with a local as with a general anesthetic.

Dr. M. A. Goldstein of St. Louis advocated local anesthesia for removing ordinary adenoids and tonsils.

Dr. Joseph C. Beck of Chicago considered ether the safest general anesthetic for the removal of tonsils and adenoids, particularly in those cases where the operator had to dissect out tonsils in children. In adults cocaine and adrenalin could be used.

Dr. Edwin Pynchon of Chicago said the selection of the anesthetic depended entirely upon the age of the patient and the condition of the tonsils. In children, in whom the tonsils protruded, he thought it was the best way not to administer a general anesthetic. When the tonsil was buried and had to be carefully dissected out, a general anesthetic was necessary. He favored local anesthesia whenever possible.

Dr. Derrick C. Vail of Cincinnati believed in giving a general anesthetic for these operations.

Dr. H. W. Loeb of St. Louis endorsed the removal of ordinary adenoids and tonsils without general anesthesia.

Dr. John F. Barnhill of Indianapolis said that usually adenoids could be removed so simply and quickly, without pain, that one was not justified in giving a general anesthetic. However, general anesthesia was sometimes necessary.

Dr. George F. Keiper of Lafayette, Ind., had never found it necessary to induce complete general anesthesia for the removal of tonsils or adenoids, because when there was

complete general anesthesia the danger from the anesthetic itself was greatly increased.

Dr. Wilbur W. Bulette of Pueblo, Col., reported the death of a child, five years of age, from general anesthesia for the removal of adenoids and tonsils.

Dr. H. W. Loeb of St. Louis, Mo., presented a number of specimens and original drawings, showing the anatomy of the nose and accessory sinuses.

Submucous Resection of the Nasal Septum.—Dr. Robert Levy of Denver pointed out the indications for this operation. He said that the window resection presented the ideal method for the correction of certain deformities of the septum which no other operation had ever offered. A contraindication to all operations upon the nasal septum was the existence of syphilis, either hereditary or acquired. He did not wish to detract from the importance and immense value that the submucous resection of the nasal septum offered. It was the most ideal operation for deflected septum. It was, however, an operation requiring a decided perfection of manual dexterity and perfect technique. It was also an operation which required more endurance and consequently produced more shock on the part of the patient; therefore, before deciding upon its performance, the symptoms should be weighed carefully and judgment exercised.

Evils of Mouth-Breathing.—Dr. C. P. Linhart of Columbus, Ohio, said that many cases of chronic pharyngitis were due to mouth-breathing. Even later in life, when the bones of the mouth and nose were completely ossified, the openings of the nares could be enlarged by proper breathing exercises. The following axioms were recommended for keeping the nose in a normal condition: Cool living rooms; well-ventilated sleeping rooms; cold bath, especially for the neck and spine; dry clothing; simple foods; regular habits; moderate daily exercise, and breathing through the nose.

Treatment of Hypertrophic and Intumescent Rhinitis.—Drs. E. Fletcher Ingals and Stanton A. Friedberg of Chicago contributed a joint paper on this subject. The authors drew the following conclusions: "(1) The galvanocautery, when properly used, offers one of the best, if not the best methods for the treatment of the intumescent and hypertrophic forms of rhinitis. (2) The dangers of middle ear infection have been greatly exaggerated, not any case in the series, and only one among several thousand cauterizations, having come under their observation. (3) The liability to adhesion formation is not great, providing sufficient care is taken not to injure the opposite septal mucous membrane, and providing, also, in cases in which the subsequent swelling is marked, a probe is passed between the opposing surfaces in four or five days. (4) A 4 per cent. solution of cocaine is sufficient in the vast majority of cases to induce complete local anesthesia, three to six applications on a cotton-wound flat applicator being sufficient for this purpose. As a result of experience, especially in cases of marked intumescence, they believe that a spray of adrenalin materially assists in producing anesthesia. (5) The objection that the galvanocautery destroys too much of the mucous membrane does not obtain, if the cauterization is linear, and if it is done properly, whereby very little mucous membrane is destroyed. (6) Scab and crust formation does not occur any oftener following cauterization than after other nasal operations; in fact, it was noted in but very few instances, and in some of these a change in the spray solution caused a cessation of this trouble. (7) No packing was needed to prevent hemorrhage, and this factor makes the discomfort following the operation very much less than after some other methods. (8) There is very little pain after galvanocauterization of the turbinated bodies."

Dr. John J. Kyle of Indianapolis reported a case of abscess of the temperosphenoidal lobe, of otitic origin.

Dr. W. R. Dabney of Marietta, Ohio, discussed the subject of acute osteomyelitis of the temporal bone.

Dr. Max A. Goldstein of St. Louis, Mo., talked on the treatment of perforation of the nasal septum.

Medical Items.

Cancer as a Cause of Death in Assured Lives.—R. Hingston Fox, who is thoroughly conversant with life assurance statistics, states that the rise of the cancer death-rate has affected women less than men. This may be due to the fact that the disease in women is in a great majority of cases on the surface of the body or in the pelvic organs, where it is comparatively accessible. He believes that the family history of cancer in the patients who died of that complaint was far more frequent than in the case of applicants generally. He points out one important feature about a family history in malignant disease in a male applicant. It is of less importance in earlier life, and of increasing moment to those who apply later. This is contrary to the rule for the value of a morbid history, namely, that it diminishes as age advances, as is especially shown in the case of tuberculous disease.—*The Medical Examiner and Practitioner.*

Health Reports.—The following cases of smallpox, yellow fever, cholera, and plague, have been reported to the Surgeon General, Public Health and Marine Hospital Service for the week ending March 17, 1906.

A NEW INSTRUMENT FOR MEASURING ALL THE DIAMETERS OF THE PELVIS IN THE LIVING WOMAN.

BY SIDNEY D. JACOBSON, M.D., M.R.C.S.(Eng.), L.R.C.P.(Lond.)
NEW YORK.

VISITING SURGEON, HOME FOR AGED AND INFIRM, YONKERS; ADJUNCT ATTENDING GYNECOLOGIST, SYDENHAM HOSPITAL, NEW YORK.

THE act of childbirth may, technically speaking, be divided into two factors: (1) The expulsive power of the uterus and its accessories in this act, namely the diaphragm and abdominal muscles; and (2) the resistance to this expulsion offered by the soft parts and (more particularly) the bony walls of the pelvis.

Of the first of these two factors very little is known. It has been estimated that the expulsive power of the normal uterus at term is equal to about 50 pounds. How much this is augmented by the abdominal muscles is problematical, and I have reasons for believing that the accessory muscles play a very unimportant part.

Of the second factor, that of resistance to the passage of the child, even less is known, except that in a general way this will depend mostly upon the relative size of the fetal head and the maternal bony parts.

If the bony ring through which the child must pass were in every case of the same size and shape, Obstetrics would be one of the simplest branches of medical practice. That this is not so is a notorious fact, and I believe that it would be difficult to find two pelves exactly alike in size and conformation. The practice of midwifery to-day is truly a groping in the dark, because of our ignorance of the most elementary knowledge concerning the mechanical act of childbirth. To speak plainly,

1. We cannot determine the power which the woman has at her command wherewith to propel the child.

2. We cannot measure the child.

3. We cannot measure the cavity through which the child must pass.

In working out this problem in dynamics the medical attendant has no accurate facts or figures to base his calculations on. The result is that midwifery is full of surprises to both the patient and the physician. If this is true in normal births, it is doubly true in abnormal ones, when a disproportion exists between the size of the maternal passage and that of the fetal head.

Before going into that subject more fully, and by way of leading up to it I may perhaps be pardoned far casting a short retrospective glance at the history of our art.

There cannot be any doubt that of all branches of medicine the very first to be practised was Obstetrics, because children have been born as long as the human race exists.

The savage in travail writhing on her bed of leaves in a cave of the primeval forest was attended by her fellows, who were attracted towards the scene by the cries incident to the pangs of labor. This assistance or help, crude as it must have been, was the beginning of one of the noblest of sciences —that of midwifery. The early Egyptians used to be delivered on the banks of a river, the umbilical cord was cut with a sharp stone and the newly-born child wrapped in the head-shawl worn by one of the bystanders. There exists a very old work written in India, called "Susruta Ajur Veda," which dates back into the gray dawn of civilization, the tenth or ninth century before Christ. It is an encyclopedic work and contains a mixture of quaint laws, doctrines, and mysterious beliefs. According to Müller[1] this work contains some allusion to Obstetrics and even an indication of knowledge of the existence of contraction of the pelvis.

Gradually the older and more experienced of her sex took up the aid of the parturient woman as a business or trade, and thus it came about that midwifery was established. There is evidence to show that the ancient Hebrews, Greeks, and Romans had midwives. In those days it was considered scandalous for a man to be present at the bedside of a woman in labor, therefore the medical profession was barred. The surgeons of that time must have had very fantastic and unreal ideas of the process and progress of labor, and their difficulties must have been enormous when called in consultation to cases of pathological childbirth, when they themselves were without experience in normal labor. This state of affairs prevailed until the time of King Louis the XIV, the lewdness of whose Court was proverbial. The courtesans frequenting the same had no scruples about employing male physicians, and thus man was finally permitted to study and treat normal as well as pathological labors. Up to that time it was believed and taught that the normal position of the child in utero was always head downwards and that it was born by its own unaided efforts; furthermore, that its delivery was effected by the child stretching out its legs, and that by bracing its feet against the fundus of the uterus the baby literally bored its way head foremost through the maternal passages into daylight. Labor was supposed to begin on the child becoming hungry (Bumm[2]). The history of Obstetrics in a most fascinating study, but space forbids my going further into the subject.

The Normal Pelvis.—For our purpose the normal adult female pelvis may be taken to measure as follows at the inlet:

Superior conjugate or antero-posterior diameter of the brim	11 cm., or 4¼ inches.
Transverse diameter	13 cm., or 5¼ inches.
Oblique diameter	12 cm., or 5 inches.
At the outlet:	
The inferior conjugate from symphysis to junction of sacrum and coccyx	11½ cm., or 4¾ inches.

*Read at a meeting of the Section on Obstetrics of the New York Academy of Medicine.

Transverse or intertuberal
diameter ..... 11 cm., or 4½ inches.

It would be obviously incorrect to measure the inferior conjugate from symphysis to tip of coccyx, as this bone can be moved backwards two or more centimeters by the advancing child's head.

These measurements are given as normal by most recent authorities, and my experience, which comprised the digital and instrumental measurement of about 1,000 pelves, on the cadaver as well as on the living woman, practically coincides with this. However, these figures do not hold good for pelves showing racial characteristics such as in the Negress or Mongolian woman. Though to me very interesting, I shall have to at present forego a discussion of this study, but hope to publish the results at a future time.

During labor these measurements may be increased in certain directions owing to the physiological softening and slight lengthening of the pelvic ligaments, and the conjugate diameter may be lengthened one-half centimeter by the patient assuming Walcher's position, namely, with her thighs hyperextended. I doubt whether any material increase is gained in this way.

If any pelvic diameter is shortened the pelvis is said to be contracted in that diameter. It may, however, be contracted in more than one, or in all its diameters, which will produce regular or irregular contraction, the pelvis changing its shape as well as size accordingly.

Contracted Pelvis.—Cohnstein's[3] definition of contracted pelvis is as follows: "A contracted pelvis is one which is an obstacle to the delivery of a normally sized fetal head at term." It is admitted on all hands that contraction of the female pelvis exists in many cases; some authors state in as many as 14 to 20 per cent. (Runge[4]). The latter author points out that contracted pelvis may be counted among the most important obstacles in the whole combined pathology of labor. He says that up to the present time we are not possessed of a method for the measuremnt of the diameters of the true pelvis, but are dependent upon certain easily made external measurements and one or more internal ones. From these we try to form a judgment of the general character of the pelvis.

In a slightly contracted pelvis the first labor may be happily terminated; whereas each succeeding labor becomes harder and harder. One cannot judge the size of the pelvis from the size and build of the woman. Even tall and well-built women may have irregular and contracted pelves.

A knowledge of the pelvic capacity of the parturient woman was always considered desirable but never obtainable in the living. Shroeder[5] says: "The decision as to how small or how large a given pelvis is, constitutes one of the most difficult tasks in midwifery." We are not able to differentiate between a flattened pelvis and one genrally contracted and asymmetry cannot be demonstrated on the living patient at all. Martin[6] finishes a chapter on the subject as follows: "The dangers which threaten the mother in case of contracted pelvis are not only those arising from a protracted labor, but more especially from injury of the maternal soft parts. In consequence of the passage of the child through the narrow space, tears, hemorrhage, inflammation, sloughing, and even death of the patient may occur. If the patient survives, communications between the bladder and vagina or rectum and vagina may be established and through these urine and feces be constantly and involuntarily dribbling. The child may suffer considerably from injury to its scalp or even indentation of its skull bones. It may die at once or some days later. In these cases rupture of the uterus may occur, and is usually fatal to the child and often causes death of the mother also."

According to Braun,[7] relative contraction, namely the acquired form, is of great clinical importance. Relative contraction may be due to carcinoma, enchondroma, sarcoma, echinococcus, formation of osteophytes or exostoses, anomalies of formation of the coccyx, and even the extraordinary development of normal bony projections, as for instance the spine of the ischium. About a year ago I saw a case of excessive callus formation at the site of fracture in a woman's pelvis which might easily have caused obstruction to labor. Even in the most deformed pelvis, however, an exception to the general rule may occur if halisteresis cerea, namely a waxy condition of the pelvic bones, exists. In such a case the bones are so pliable that delivery of the child will sometimes occur contrary to all expectations. We must agree with Braun that "The examination of the pelvis by measurement is of the utmost importance and is the most difficult task of the obstetrician."

Dührssen[8] says that for the diagnosis of contracted pelvis or of some special variety of such, pelvic measurement is essential. Furthermore, that kyphosis situated low down should arouse a suspicion of the presence of transverse contraction of the pelvis. That a funnel-shaped pelvis exists will be indicated only during the progress of labor by the head becoming jammed in the pelvic outlet.

According to Skutsch[9] it is about 350 years ago since the existence of contracted pelvis was recognized. Julius Cæsar Aurantius was the first to demonstrate that a narrow pelvis is the principal cause of difficult labor. There was no correct anatomical knowledge until the sixteenth century; neither was the mechanism of childbirth understood before that time, and it was taught that during labor the bones of the maternal pelvis separate. Even the correct anatomical description of the bony pelvis by Vesalius [10] was unable to cope with that ingrown belief. It was not until the eighteenth century that the works of Deventer[11] and De La Motte [12] were published and caused more advanced views to prevail. During the eighteenth century Smellie of England[13] and Baudelocque of France[14] threw much light upon the subject. Michaelis[15] and Litzman,[16] also the two Steins—Senior[17] and Junior[18] contributed to our knowledge of the subject, thus keeping up the reputation of Germany in this field of study. It is Smellie's undying merit that he was the first to teach palpation as a means of diagnosticating the diameters of the pelvis. His method is still in vogue, although from time to time instruments have been devised to displace it. The method, however, is quite inadequate for the demands of modern midwifery. It is carried out as follows: The index and middle fingers are passed into the vagina and pushed up towards the sacral promontory. Ordinarily this cannot be reached. In that case it is assumed that the pelvic conjugate diameter is not contracted. The hand in then withdrawn. If the tip of the middle finger managed to reach the promontory the distance from the point where the radial side of the index finger pressed up against the lower edge of the pubic symphysis to the tip of the outstretched middle finger is measured. This is the diagonal conjugate. To find the length of the true conjugate from one-half to one inch is subtracted. Authorities differ as to the amount which should be subtracted.

The most important elements of error which may

creep into the calculation are: (1) the unknown height and thickness of the pubic bone, and (2) the possible existence of a false promontory overhanging the real one, thus greatly shortening the conjugate diameter. No one even pretends to be able to determine the transverse or oblique diameter of the brim by the manual or digital measurement.

The second method of measuring the female pelvis is the instrumental, and its development is a most interesting chapter for study. It does not reach back much more than 100 years. A great variety of pelvimeters have been constructed from time to time, and some men have even invented several kinds. The records show quite an imposing array of names of physicians, the best known of whom are, Baudelocque, Matthieu, Breisky, Stein, Creve, Asdrubalin, Jumelin, Lazarevitz, Aitken, Contouly, Harris, Earle, Salomo, Desberger, Bowin, Kiwish, Beck, Kurz, Crouzet, Winckler, Howitz, Kabierski, Wellenbergh, Van Huevel, Szymanowski, German, Freund, Turner, Breit, Küstner, Mayer, Stark, Simeon, Beron, Wigand, and Aveling. It would be a time-consuming and thankless task to describe in detail all the pelvimeters constructed by these and other less famous authors.

Some of these instruments were for external measurement, others for internal, and the rest for externo-internal use. A number, like that of Stein, were merely graduated rods or catheters. Some were hollow finger tips which were slipped over the index finger like a thimble, and made long enough to reach the sacral promontory. Some were shaped and worked like scissors and had a gauge attached. Some were sliding rods to measure the thickness of the pubic bone and to deduct this from the true conjugate. Some were fanciful curvilinear compasses. Some were constructed on geometrical lines from which the angles could be counted and the diameters figured out. One was a leather gauntlet laced around the operator's wrist, on which a scale was marked and a sliding knob worked up and down the scale. To the knob a string was attached which was tied around the thumb and index finger by means of a loop. As the index finger stretched out to find the sacral promontory the knob would be pulled along the scale and would indicate how far the finger tip had traveled. Meyer pierced his thumb and index finger nails with a threaded needle so as to get the proper amount of friction for the thread. German lauded his instrument highly and pressed its claims to being not only a pelvimeter but also a funis repositor, sling carrier, uterine sound, irrigating tube, and catheter. It can be used indifferently well for many purposes but not especially well for pelvic measurement. Wellenbergh, Szymanowski, and Van Huevel first took external measurements of the pelvis, then measured the thickness of the bones and soft parts constituting the pelvic walls. They added the latter and subtracted from the former, and thus arrived at their conclusions of the diameters. They were the first to make an attempt at finding the transverse diameter of the brim.

Breit constructed an instrument for the internal measurement of the transverse diameter of the brim. The use of this instrument is so painful that it cannot be used in some cases at all. Freund and Skutsch invented instruments with leaden arms which can be bent by the operator at will. They are difficult to use. Van Heuvel, who has been prolific in the invention of devices for measuring the female pelvis, constructed one to be used on the patient while she is in the upright position. She stands with her legs spread apart, her body bent forward, and her hands grasping the back of a chair for support. The physician stands, or rather kneels, behind the woman and directs the instrument. To a woman of refinement there is something so indelicate, if not revolting, in this proceeding and it is so undignified a position for the doctor that it has not come into general use, at any rate in America or England. Kiwish introduced one blade of his instrument into the patient's urethra. I believe that this procedure may be considered unjustifiable. The pelvimeter of Baudelocque is used to this day. It is well-known so I will not take up time and space to describe it.

I agree with Busch[19] that we must not deceive ourselves, but admit that instrumental pelvimetry has advanced to such a slight degree that we cannot even distinguish positively between a flat pelvis and one which is generally contracted. We read in the writings of our best pelikologists that a positive differentiation between these two types of contracted pelvis can be made *only during the progress of labor.* Baudelocque thought that by use of his external pelvimeter he had made internal measurements superfluous. In this he was mistaken. The obstetricians of our day are just as badly mistaken if they think they can determine the transverse diameter by their external measurements.

Naegele[20] says that in measuring the external conjugate three inches must be deducted to allow for the thickness of the pelvic walls. In very fat women more will have to be deducted. Experience, however, has shown that in contracted rhachitic and osteomalacic pelves the thickness of the pelvic walls varies so much that external measurements give thoroughly unreliable results. Breisky[21] says that the most ingeniously constructed instrument has not been able to dislodge the method of digital measurement to find the diagonal conjugate, as taught by Michaelis.

Summary.—Without putting a forced construction upon any part of the foregoing evidence I believe the following conclusions are warranted:

1. Under ordinary circumstances the normally sized and shaped maternal pelvis is the great obstacle to the delivery of the normal fetal head at term.

2. The maternal pelvis is rather frequently contracted in one or more of its diameters.

3. If the pelvic contraction is slight spontaneous or instrumental delivery may take place without injury to mother or child.

4. If the contraction is greater in degree delivery of the child by instrumental aid will be necessary and in the highest grades of pelvic contraction delivery through the natural passage is impossible.

5. The size and build of the woman afford no criterion as to the size and shape of her pelvis.

6. On the exact degree of contraction will depend the choice of method of delivery of the patient, or the choice as to which of a number of different operations is to be performed in order to save the mother, or child, or both.

7. It is therefore essential to be able to measure correctly the obstetric pelvis, if modern midwifery is to be deserving of its name.

8. So far no one has been able to accurately measure the pelvis in the living woman, and the methods in vogue are but poor and inaccurate attempts at guessing.

The instrument which I desire to bring forward, and pictures of which accompany this article, will enable the physician to measure easily, rapidly, accurately, and painlessly, all the important diameters of the pelvis in the living woman. It will also enable him to determine the shape of the pelvis and in the presence of abnormalities, such as callus, tumor, or deformity, find exactly how much room is available

for the child to pass through. It is constructed of steel and consists of two branches, hinged together at the bottom end, in the form of calipers. It is composed of an outer semicircular branch and an internal irregularly S-shaped branch, each one being attached to a handle. It has a movable gauge which slides on a grooved track and which can be fixed in any part of this track by a set screw. The internal or movable branch is attached to its handle by a pin and socket and has a loop on each side into which a sliding catch can be made to slip which will securely hold the inner branch in either of its two positions, namely, when it points toward its fellow or when it points away from it. The upper ends of the branches are ball-pointed and these points or tips can be made to separate about twelve inches. The distance of their separation is indicated on the sliding gauge.

A leather belt about two inches wide, graduated in inches, halves, and quarters, beginning at the buckle and reading from right to left, accompanies the instrument. (See Fig. 1.)

The internal or movable branch is graduated in inches, halves, and quarters from the ball at its top end downwards.

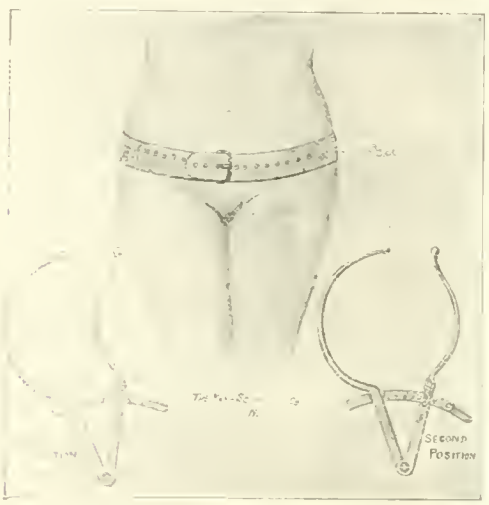

FIG. 1.

The modus operandi is as follows:

The bladder and rectum being empty, the patient is laid on her left side upon a table and her knees are drawn up and kept that way. The belt is put around her hips so that the extreme end of the buckle is just over the symphysis pubis and exactly in the median line of the body. The belt in passing around should be about in the center of the sacrum. The belt is buckled on so as to be fairly tight. Two fingers of the right hand are lubricated with soap and passed into the vagina. The pelvis is now thoroughly explored. The points to be particularly noted are the size of the introitus, the rigidity or relaxation of the perineum, the capacity of the vagina and its direction, the degree of abdominal tension as shown by low situation of the uterus and bulging downwards of the vaginal walls; the pelvic walls are explored for any abnormality and an attempt is made to reach the sacral promontory. In normal cases the fingers will not reach the promontory. It is presumed that the physician who uses this instrument is reasonably familiar with the anatomical landmarks of the pelvis which can in ordinary cases be palpatated through the vagina and rectum. For this reason some very elementary and self-evident instructions will be here omitted.

The fixed branch of the instrument always remains outside of the body, therefore will be named the outer or stationary branch; the other is used internally and will be called the internal or movable branch. The latter can be made to turn in its socket at the handle so that it may point away from its fellow. This is assuming the first position, or it may be turned around to point toward its fellow and thus assume the second position. The object in view is to make the ball-pointed end of the movable branch travel from one particular bony point on the internal surface of the pelvis across the pelvic cavity to a bony point exactly opposite, thus traversing the cavity in a certain diameter. As the distance traveled by the tip of this branch is faithfully recorded on the gauge it is obvious that the record on the gauge will show the length of the diameter traversed. The fixed or outer branch must be kept on one spot during this time, and it is of use only to give a fixed point of support for the instrument while in action.

Assuming that the patient is properly placed, the graduated belt in its proper location, and the instrument in position, the following maneuvers *will give the exact length of the true conjugate diameter of the brim.*

FIG. 2.

FIG. 3.

1. Place the tip of the fixed branch on the strap over the middle of the sacrum. (See Figs. 2 and 3.)

2. Place the tip of the movable branch in the middle of the posterior or vaginal surface of the symphysis pubis.

3. Move the sliding gauge firmly against the handle of the movable branch and fix it there with

the set screw. With the index and middle fingers of the right hand guiding the internal branch, depress the posterior vaginal wall and with its tip probe for the sacral promontory. (See Fig. 5.)

Fig. 4.

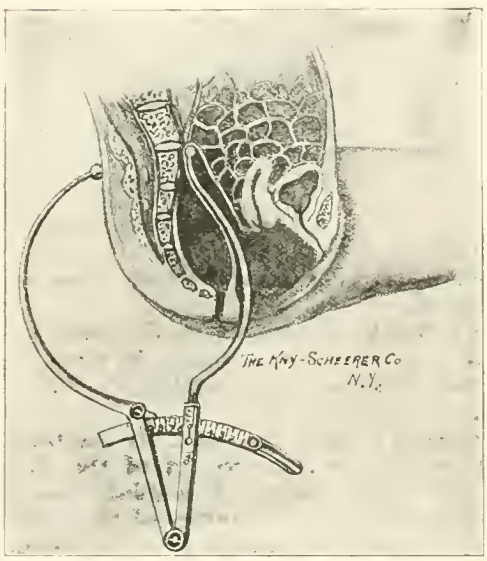

Fig. 5.

5. This will be distinctly felt as a hard bony ridge or prominence. While holding the instrument steadily, read off the number of inches recorded on the gauge.

Fig. 6.

To find the transverse diameter of the Brim:

1. Note the number on the graduated belt which is exactly in the median line of the sacrum.

2. Place the tip of the fixed branch on the strap at exactly half that number of inches. This will put it over the center of the pelvis.

3. With the movable branch *in the first position,*

Fig. 7.

go straight across the middle of the pelvis and up high enough to reach the bony ridge which is the ilio-pectineal line. (See Fig. 6.)

4. Move the sliding gauge up firmly and set it with the screw.

5. Withdraw the movable branch, make it assume the second position, and make its point reach up to the ilio-pectineal line or ridge toward you facing the tip of its fellow on the strap. (See Fig. 8.)

6. Read the number of inches recorded on the gauge.

Fig. 8.

Sometimes it is of interest *to measure the oblique diameter of the Brim.* In that case do as follows:

1. Read the number on the belt exactly in the median line over the sacrum.

2. Subtract one-fifth of that number and place the tip of the fixed branch on the strap at that spot; this will be just over the sacro-iliac joint.

3. With the movable branch in the first position

within the vagina find the left iliopectineal tubercle diagonally across the pelvis.

4. Move up the sliding gauge and set it with the screw.

Fig. 9

5. Withdraw the movable branch, make it assume the second position, and with its tip find the right sacroiliac joint so that as the tips of the two branches face each other they include the right posterior pelvic quadrant.

6. Read off the number of inches indicated on the gauge.

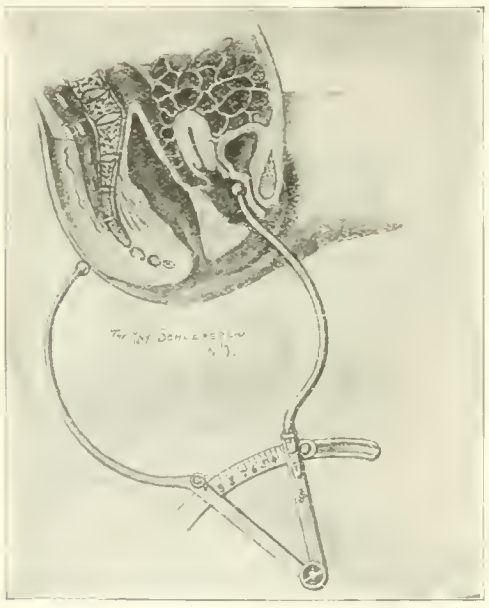

Fig. 10.

To find the inferior conjugate or conjugate of the Outlet:

1. Place the tip of the fixed branch on the strap as low down as possible in the median line of the sacrum. (See Fig. 10.)

2. The tip of the movable branch in the first position finds the lower edge of the symphysis pubis.

3. The movable branch is withdrawn and its tip in the second position made to touch the sacrococcygeal joint. (See Fig. 11.)

4. Read the number of inches recorded on the gauge.

To find the transverse diameter of the Outlet:

1. Place the woman on her back with her knees well drawn up.

2. Mark the skin with a pencil or dermatograph

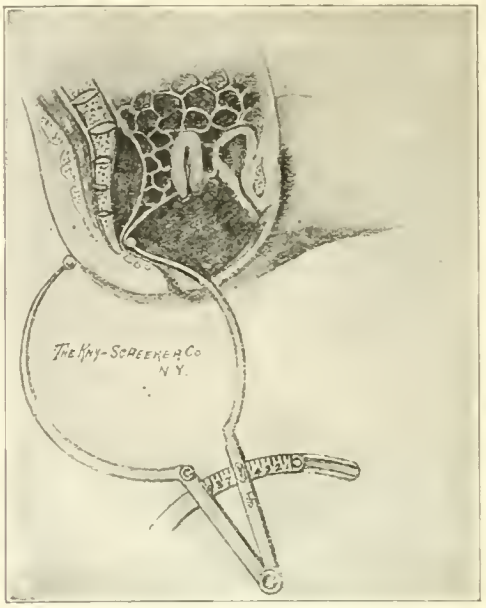

Fig. 11

over the inner edges of the tuberosities of the ischium.

3. Measure the distance between them with the instrument.

The ischial tuberosities are easily found when the woman is in the described position by pressing firmly with one or more fingers against the flesh at the buttock.

Personally I am in the habit, for the purpose of rough and ready measurement of the transverse diameter of the outlet, of pushing four fingers abreast between the tuberosities of the ischium the tips of the fingers pointing towards the patient's urethra. If four fingers abreast are admitted comfortably between the tuberosities it may be assumed that no contraction exists. (See Fig. 12.)

Fig. 12.

The above appear to be the most important diameters of the female pelvis for purposes of Obstetrics. However, under some circumstances, as in callus, tumor, or other kind of obstruction causing irregu-

lar contraction, measurement in other planes of the pelvis may be found necessary.

In making these, if the general rules laid down in the above are followed and the method of pelvimetry is adapted to the case in hand, no difficulty need be feared.

A few points might be well borne in mind, however; namely:

If the introitus is small (and this is not at all common in the last months of pregnancy) or if the perineum is rigid, an assistant may retract the latter with a Sims speculum to give room for manipulation.

In case of great contraction of the vagina from scarring due to a previous severe forceps labor or the ill-advised plastic operation of some surgeon desirous of making a particularly small introitus, the sacral promontory can be easily reached through the rectum inflated with air. The bony points stand out with startling distinctness on examination through the inflated rectum. If all efforts at examination fail, recourse can in exceptional cases be had to anesthesia. I have found it necessary only once to anesthetize a patient; this one was an hysterical onanist who closed her knees convulsively and screamed every time her vulva was touched. In case of very fat women with bulging vaginal walls and great abdominal tension, making it difficult to map out or recognize the bony landmarks, if we put the patient in the knee-chest position and retract the posterior vaginal wall with two fingers so as to allow the pelvic contents to gravitate toward the diaphragm, air entering suddenly will cause the vagina to balloon out. It is perfectly astonishing how easily the bony landmarks can be palpated then, and the pelvis measured.

The pelvic diameters can be measured ordinarily in about five minutes. The pain to the woman, unless violence is practised, is trifling. Some do not complain at all. Some of those who did complain of pain I found on examination to have a fissure of the anus. Swabbing this with a 5 per cent. solution of cocaine made the measurement painless. That the results are accurate I have demonstrated to my satisfaction on the cadaver repeatedly. It is almost superfluous for me to add that all gentleness should be used in the handling of this steel instrument so as not to cause unnecessary pain.

My acknowledgments are due to Mr. Richard Kny of the Kny-Scheerer Company for his uniform courtesy, and to Messrs. Wm. A. Winter and Charles Sorensen for valued assistance and suggestions in the preparation of the plates and construction of the apparatus.

The instrument described herein is presented to the profession with due modesty as becomes an ardent though humble student seeking the Light.

THE TREATMENT OF MENINGOCOCCUS MENINGITIS IN THE FIRST MEDICAL DIVISION OF BELLEVUE HOSPITAL DURING THE EARLY SUMMER OF 1905.*

By EDMUND L. DOW, M.D.,

NEW YORK.

ASSISTANT VISITING PHYSICIAN, BELLEVUE HOSPITAL.

Through the courtesy of Dr. George R. Lockwood, and through the assistance of an unusually efficient house staff, I was enabled in the early summer of 1905 to observe, and in large part to direct, the treatment of one hundred and sixteen cases of meningococcus meningitis at Bellevue Hospital. The conclusions reached I desire to place before you at this time, in order that they may, perhaps, be of service at the possible eve of another epidemic. Few statistics will be given. Statistics are of little value in so small a number of cases, limited to a single epidemic. Deep grounded opinions founded on careful, close, constant observations of individual cases are, however, of great value. The other large city hospitals admitted or retained very few cases of this disease during the latter part of the epidemic, so that the number of cases admitted to Bellevue during that time was relatively large. The meningitis ward was full of cases when I went on service on May first. Sixty-seven cases were admitted after that date, of whom forty-seven per cent. were discharged from the hospital practically cured.

To present the subject of the treatment of these cases properly before you, I shall first describe the character of the disease to be conquered, then, what measures could reasonably be expected to bring about this result, and then the means actually employed. Epidemic cerebrospinal meningitis is excited by the meningococcus. Many varieties of bacteria can excite a meningitis, but it is only the meningococcus that seems to cause the development of an epidemic. Now that the exciting organisms have been identified and studied, custom is beginning to change the former nomenclature of epidemic and non-epidemic meningitis to the more specific etiological terms, meningococcus meningitis, pneumococcus meningitis, streptococcus meningitis, tuberculous meningitis, and so on. When the meningococci gain entrance to the interior of the skull and spinal canal, and when the coverings and the lining of the brain and cord are susceptible to their presence, an intense overactivity of these tissues results. Meningitis is essentially overactivity within a closed cavity. In the meningococcus form, it is a self-limited group of processes. This overactivity is both structural and functional. Structurally the first change to be observed is an extreme dilatation of the blood vessels wherever the bacteria exist.

If we think of meningitis exhibiting during the life of the patient only the lesions revealed by the

*Read at a meeting of the Medical Society of the County of Kings, February 20, 1906.

autopsy table, we obtain a somewhat erroneous impression. One is not then apt to remember the intense congestion, the flowing blood, the absorbing lymph, and the living cells almost boiling with the activity of their protoplasm. The evidence of this intense hyperemia largely disappears at death. Its analogue is seen in the lung, during the first stage of lobar pneumonia. This congestion of the pia mater is excessive and continuous. This greater quantity of blood within the skull increases by its mere presence the amount of intracranial pressure. In a disease in which cerebral pressure is of so much importance, this fact should be emphasized.

The next important structural change is the increased active transudation of cerebrospinal fluid, somewhat modified by the intensified processes. The normal transudation of this fluid depends not only upon the physiological activity of the endothelial cells of the blood capillaries, and the mesothelium of the pia mater and ependyma, and upon the physical process of osmosis, but also upon the physical process of filtration. It is a well-known law of physics that the greater the pressure on one side of an animal membrane, in this case the blood-vessels, the greater tends to be the amount of fluid forced through to the other side, here, into the perivascular spaces. This fact is often illustrated by causing edema to appear or disappear by lowering or raising a leg in which there is a tendency to edema. Coincident wth the congeston of the blood-vessels and the increased exudation of cerebrospinal fluid the leucocytes leave the blood vessels in increased numbers and accumulate in the surrounding and lining cavities. In the meningococcus form of meningitis the leucocytes incorporate into their bodies large numbers of the bacteria. In no other form of meningitis do we find so many intracellular parasites. Because of this the meningococcus was at one time named the diplococcus intracellularis. From the cerebrospinal fluid, which is really a modified blood plasma, a certain amount of fibrin is precipitated, and then the fluid is reabsorbed by the lymphatics and the blood capillaries to circulate again throughout the body. When the cerebrospinal fluid is reabsorbed, it carries with it in solution any chemicals which were produced directly or indirectly by the growth or by the death of these bacteria. These poisons circulate everywhere throughout the body, affecting it more or less, as proved by the characteristic eruptions, and again reach the brain in a diluted form to penetrate to every brain cell in its structure where blood is supplied. In the meantime, the cells composing the susceptible brain covering and lining have been proliferating, and, to a certain extent, desquamating into the cerebrospinal cavity.

The entire picture is one of intense overactivity due to the energy bound up in the individual living body cells, and aided by the force of the increased blood pressure derived primarily from the work of the heart muscle, the *vis a tergo*.

When the fluid is secreted into the cerebrospinal spaces in increased amounts due to the greater pressure of blood and to the greater activity of the endothelial and mesothelial cells, it will accumulate in these spaces unless a commensurate absorption occurs. Inasmuch as lymphatic vessel absorption is due to the physical force of capillarity which is not affected by pressure, this cerebrospinal fluid, often, but not always, tends rapidly to increase in amount, and to attain a pressure which approximates that of the blood in the capillaries from which it was derived. This increased blood supply to the inside of the skull and the spinal canal plus the increased amount of transuded cerebrospinal fluid into the same practically closed cavity must necessarily compress all yielding structures, namely, the brain substance, the veins, and the lymphatic vessels. This pressure upon the orifices of the lymphatic ducts, when it occurs quickly, compresses them so that absorption is then greatly impeded. An analogy is found in the pleural cavity. When we relieve intrapleural pressure in pleurisy with effusion, absorption occurs. Blocking of lymphatics should occur more easily in the skull and spinal cavity than in the thorax, owing to the surrounding, non-yielding walls of bone.

However, the overactivity excited by the meningococci is not entirely structural in its nature. Functional overactivity without apparent change of structure also results in the early stages of the disease. The bacteria and the resultant poisons not only stimulate the various tissues and cells to excessive congestion, secretion, emigration, and proliferation, but also excite the neurons into excessive functional activity. This brain and nerve cell overactivity is most marked where the poisons are strongest. If they are produced adjacent to a cell or its fibers the concentration of the irritant calls for a greater release of energy. If the poisons are brought to other brain or nerve cells by the blood stream from a distance, or by the circulating cerebrospinal fluid, the dilution of the toxin by the blood or fluid permits in the more remote cells a less degree of overactivity.

Frequently the neurons that show excessive action later develop degenerations and entire loss of function either temporary or permanent. The functional overactivity and the underactivity of the various cells results in a large number of symptoms. Many of these symptoms have indirect serious consequences, such, for example, as cardiac exhaustion following intense restlessness. Moreover, in addition to the effect produced by the local or general, chemical or zymotic, action of the poisons, we have to consider the mechanical effect produced upon the neurons by the cerebrospinal fluid when this accumulates with sufficient force to compress the substance of the brain and cord. This increased pressure of cerebrospinal fluid does not always exist in a meningitis. An analogy is again found in pleurisy. The exuded fluid in a pleurisy may be reabsorbed as rapidly as it transudes, so that what is known as dry pleurisy results. If this reabsorption does not take place, we get pleurisy with effusion. In both forms of pleurisy, the membranes are intensely congested. Likewise in a meningitis, we may or we may not have an increased amount of cerebrospinal fluid remaining in the skull and spinal canal. It depends upon the various factors already mentioned. In either case, however, a certain amount of brain and cord compression occurs from the additional circumstance of intravascular blood pressure. The former is difficult to combat, the latter not so difficult. This intracerebral pressure, excessive from accumulated cerebrospinal fluid, or moderate from blood supply, produces a disturbance in the functions of the neurons, and various additional symptoms result from this alone.

After the process of overactivity has lasted about two weeks in a patient who does not die, the meningococci largely disappear from the coverings of the brain, and the structural and functional processes of the various cells approach the normal. Leucocytes no longer emigrate in such numbers from the blood vessels; congestion disappears; secreting activity of the endothelium and mesothelium lessens; and digestion of the dead leucocytes and fibrin would

again leave the subarachnoid and the ependymal spaces in the same condition as before were it not for the damage done by the previous cell proliferation. The new connective tissue and other cells have left a pia mater considerably thickened, and the orifices of the lymph vessels somewhat occluded. Absorption in many cases is thus rendered imperfect. The clear cerebrospinal fluid, now nearly normal in character, tends to accumulate within the ventricles of the brain, and within the spinal canal, and within the posterior fossa of the skull around the cerebellum and beneath the tentorium cerebelli. As a rule, the fluid continues to be absorbed from the spaces around the cerebrum above the tentorium so that the pia mater in this locality is often caused to be dryer than normal. The presence of this abnormal amount of cerebrospinal fluid occurring after the subsidence of meningitis, is known as hydrocephalus. Its accumulation is apparently due to purely mechanical reasons, although some claim that functional overactivity of the secreting ependymal cells continues to exist. Whatever may be the reasons for the development, its presence causes a functional derangement of various neurons by its mechanical pressure, with resulting symptoms usually terminating in death.

Much has been said about the closure of the foramen of Magendie being necessary to the production of a hydrocephalus. This foramen lies at the lower apex of the fourth ventricle and connects the large lymph sac covering the cord and cerebellum, with the various ventricles of the brain. I have never seen a case of hydrocephalus following meningitis in which the ventricles were distended with fluid, that did not during life give evidence by spinal puncture that the space surrounding the cord was also distended with fluid under pressure. If ventricular hydrocephalus is due only to a blocking of the foramen of Magendie, to what is the always associated distention of the subdural space over the cord and cerebellum due? We can come to but one conclusion. Fluid accumulates in the subdural space beneath the tentorium and in the ventricles, because absorption from the subdural space is imperfect. It does not accumulate in the subdural space over the cerebrum because absorption does occur there. Moreover, fluid accumulating in the lateral ventricles can expand the cerebrum so that it will be pressed tightly against the calvarium practically obliterating the subdural space over the cerebrum as shown by the flattening of the convolutions. The fourth ventricle is not large enough and is not situated so that fluid accumulating there can expand the cerebellum or the medulla or the cord. Consequently there is always a space of considerable depth surrounding the cerebellum and the spinal cord. Fluid accumulates within this space in hydrocephalus with a pressure equal to that within the ventricles.

To recapitulate briefly, the meningococcus excites for about two weeks an intense structural and functional overactivity with sometimes a resulting increased cerebrospinal pressure and with sometimes various degenerations. This is a self-limited disease. It may subside, and the patient recover. It may be followed by one or more relapses, or it may be succeeded immediately, or after an interval of several weeks, by a condition of hydrocephalus. Because the processes and conditions involve the central nervous system an unusual number of symptoms manifest themselves. Death may occur from either the meningitis or the subsequent hydrocephalus. Inasmuch as the meningitis is essentially an active process and the hydrocephalus is essentially a passive condition, the treatment of each is entirely different.

Let us consider what we may hope to do to help the patient who has meningitis. Can we destroy or nullify the poisons or the bacteria that excite the disease? Can we lessen the overactivity of those functional or structural processes which do damage? Can we support the resistance of the patient otherwise so that he may combat successfully the invading army of parasites? To the first question we must at present answer, No. The only way the poisons or the bodies of meningococci can be nullified with our present knowledge, is by assisting the patient to do it himself. Little is known as to the exact means the human body uses to make meningococcus meningitis a self-limited disease. It is known that it is difficult to cause a septicemia by the inoculation of the meningococcus into the blood of small animals, whereas a similar injection of its cousin, the pneumococcus, quickly results in septicemia and death. It is also known that leucocytes within the cerebrospinal fluid of a meningococcus meningitis contain within their protoplasm numbers of these organisms, so that it is reasonable to suppose the leucocytes are active in combating the invading parasites.

To diminish the intense cellular activity, and its untoward results, probably our best remedy lies in the use of some alkaloid of opium. A minute dose of morphine, administered hypodermatically to a patient in the early stages of a meningitis, lessens greatly the overactivity of all of the brain and cord centers. It promotes bodily rest and a saving of the necessary reserve strength. It relieves the intense pain, and the subsequent demoralization of the patient's mental condition. It permits relaxation, and establishes a harmonious equilibrium everywhere. An accessory measure which helps is to be found in the maintenance of a normal body surface temperature. This allows the blood to remain at the surface of the body, and relieves the congestion of the brain. To accomplish this, the temperature of the room or surrounding atmosphere must be that of summer heat. The skin must not become chilled. Correspondingly the body should be sufficiently clothed and the hands and feet kept warm, by stockings and hot water bottles, if necessary. The bedclothes must help to maintain the normal warmth. If they are oppressive to a hyperesthetic skin, they must be elevated. The weather and the temperature of the ward seemed to have much to do with the progress of the cases. The results were uniformly bad at the beginning of the epidemic during the cold months of February and March, and were uniformly good during the warm months of June and July. How much the temperature of the weather had to do with these results is not certain because the treatment of the cases was at those times materially different. It might be argued that the bacteria were less virulent when the epidemic was drawing to a close. Possibly this is true, because the patients developing the disease gradually became relatively fewer; but, on the other hand, the patients observed late in the epidemic entered the hospital with symptoms that were fully as severe as those seen earlier in the season. Of the forty-two patients admitted in May, twenty-one were cured. Of the four admitted in August, only one was cured. When the weather was mild, these late cases did well. If a cold night supervened, all of these late cases became worse. Outside of the question of the virulence of the microorganism it did seem to be proved that the temperature of the room had much to do with the course of the disease. Warm baths maintained for some time and repeated frequently accomplish a good result in like manner. They lessen the blood supply to the head and promote muscular relaxation.

They are not always practicable. Frequently they induce voluntary struggling on the part of a child. Often the shock to the sympathetic nervous system is, in the case of meningitis, injurious. Warm baths for a number of patients require the services of many nurses in a hospital ward, and this is a serious objection to their use. When it is practicable to have extra nursing for a patient, and when the nurses thoroughly dry the skin after a bath, without subjecting the patient to injurious draughts of air, and when the patient does not object to the bath, much benefit is sometimes obtained from its use.

Another method of lessening intravascular pressure was tried in Bellevue Hospital last year with much success. It was noticed that when a patient was deemed well enough to be allowed an extra pillow under the head, he improved much more rapidly than was expected. This led to the trial of the effect of posture upon these cases at an earlier stage. It was observed that when the bodies of patients with severe tubercular meningitis with extreme motor restlessness were supported for a time into a half upright position, the active symptoms often disappeared rapidly, and the patient apparently slept quietly. Occasional observation was, however, necessary to ascertain the degree of elevation needed to obtain a favorable result. The effect of this brain anemia did not apparently lengthen the course of tuberculous meningitis, but merely ameliorated the distressing symptoms. In the case of meningococcus meningitis, the patients seemed to be uniformly helped by its use. The symptoms were less marked, the course of the disease somewhat shorter, and the convalescence more rapid. In the cases that died, it apparently was of benefit, and delayed the fatal termination. It was apparently of little value in the cases of hydrocephalus, in which, as I have stated, the trouble is not too much blood going to the brain, but rather too much fluid held in the brain. The posture treatment of meningitis has been claimed by some to work by favoring drainage of the cerebrospinal fluid. Inasmuch as the absorption of this fluid is chiefly performed by the lymphatics where capillarity is the entire physical force, gravity could not be expected to be of great assistance. In the employment of posture as an aid to lessen the amount of cerebral activity and cerebral intravascular pressure, care should be taken not to abuse the advantage by producing an injurious amount of cerebral anemia. A reasonable amount of blood is necessary for the physiological processes of the cardiac, respiratory, and other centers. If the posture becomes so elevated that the intravascular pressure diminishes until it equals in degree the already existing pressure of cerebrospinal fluid, the blood capillaries tend to become compressed, and blood is prevented from entering freely to the finer parts of the brain. A slight elevation of the head and shoulders usually suffices at first to produce beneficial results, and this is to be increased rapidly as convalescence proceeds.

Ice to the head may be of some value. If its pressure annoys the patient, its advantages are not so great. Lumbar puncture during the first few days of a meningitis, or of its relapse, is of real service. It apparently acts by relieving the pressure of the cerebrospinal fluid so that absorption becomes again possible. An analogy is seen in pleurisy with effusion. It is apparently of no permanent value in the subsequent hydrocephalus in which the pia mater is permanently damaged, although it may then produce a very temporary amelioration of the symptoms. It is possible that autodrainage may solve the problem in these difficult cases.

Before the subject of intracerebral pressure is dropped, it should be stated with much emphasis that the stimulants which are frequently given in this disease are positively harmful. Their use is irrational. The brain always has too much blood, and has been stimulated to the limit by the poisons of the bacteria. The administration of other stimulants aggravates this condition. This is an error frequently committed by uninstructed members of the house staff. They often administer stimulants to a patient suffering from another disease with benefit, and they jump to the conclusion that the condition of the pulse in meningitis requires a like stimulation. If we inspect the histories of many cases of meningitis reported by some observers, where conclusions are reached as regards treatment by anything on trial, such as antitoxin, horse serum, lysol injections, lumbar puncture, baths, and other various remedial measures, it will in a large proportion of cases be noted that the amount of stimulation administered has not been taken into account, although it is frequently unadvised and excessive. The experimental conclusions drawn in some of these cases are therefore inconclusive. Possibly there are two exceptions to these statements. Minute doses of alcohol in the form of whiskey or brandy often seem to do real good. It apparently acts by maintaining the peripheral cutaneous circulation, and by affording a certain amount of latent energy. When the first sound of the heart is absent, the second pulmonic sound accentuated, and the hands and feet cold and blue, occasionally minute doses of digitalis benefit, but strychnine, adrenalin chloride, nitroglycerin, atropine, and large and continued doses of digitalis, whiskey, or any alcoholic food do immense damage, and increase the liability to hydrocephalus, if the patient lives long enough.

Of much more importance to the patient in the treatment of this disease than any measure mentioned, with perhaps the possible exception of the use of morphine and the elevation of the head and shoulders, are the measures calculated to sustain and fortify the patient. These include forced feeding, by gavage, if necessary; plenty of fluid; the usual means to relieve constipation, a condition which frequently causes fever and an exacerbation of symptoms in a convalescence. They also include a plentiful supply of pure air to the lungs, and an abundance of sunshine to the body, remembering that when there is photophobia the eyes should be protected from too much light. Nothing seemed to help the meningitis patients at Bellevue Hospital so much as being kept in beds put out of doors when weather permitted, where the patients could secure an abundance of sunshine, and warm, fresh air. Probably the best treatment of meningitis in the winter, when this is not possible, would be a trip to a warm southern climate where these conditions prevail.

Now, let us consider the routine treatment as actually practised in the First Medical Division during the early part of last summer. When there was admitted to this division a patient suffering apparently from an active meningitis, he was at once put to bed in a warm, darkened, quiet room, with his head and shoulders slightly elevated. If the pains in the head were severe or the restlessness extreme, the patient was then given a minute dose of morphine solution hypodermatically. This was repeated until comfort or quiet was obtained. If it did not control these symptoms, a warm tub bath was administered, in which the morphine seemed to become effective, so that subsequent baths were not often necessary. As before mentioned, the ordinary hos-

pital ward of meningitis patients does not contain nurses enough to give systematically many tub baths. In the meantime a history of the duration of the patient's illness, enabling us to give further treatment, was obtained, when possible, from the friends or relatives. This information is frequently sufficient to allow us to determine whether the symptoms are those of a beginning meningococcus meningitis, a relapse of a meningococcus meningitis, a beginning tuberculous meningitis, or a hydrocephalus—a diagnosis not always easy to make from external symptoms alone.

After these primary measures the patient's lumbar canal was punctured and a reasonable amount of fluid was allowed to flow into sterile test tubes. This withdrawal of fluid is not always possible, unless careful technique is employed. It may often be easily obtained when otherwise difficult, by flexing forcibly the entire trunk and head. Lumbar puncture serves two purposes. It is a means of accurate diagnosis, and it often relieves urgent symptoms and ameliorates the course of the disease. Inasmuch as the primary diagnosis is of so much importance in the treatment, a word is necessary as regards the conclusions to be drawn from the appearance of the fluid. Fluid obtained from puncture of the spinal canal, when turbid, usually denotes an acute meningitis of a nontuberculous nature. It may be from a primary attack, or it may be from a relapse. This turbidity is due chiefly to polynuclear leucocytes. The turbidity may vary from a slight milkiness of the fluid to a creamy pus. In meningococcus meningitis, large numbers of the leucocytes contain the organism, which, because of this feature, was formerly called the *Diplococcus intracellularis*.

When the fluid obtained is clear, it signifies either the fluid from a tuberculous meningitis, or the fluid from a hydrocephalus. The hydrocephalus may have followed an acute meningococcus meningitis. When normal cerebrospinal fluid is centrifuged, and the resulting precipitate is smeared upon a glass slide and examined by a one-twelfth inch oil immersion lens, it shows about nine to twelve leucocytes to a hundred fields. The fluid from a hydrocephalus does not contain a greater number. The fluid from a tuberculous meningitis shows many more leucocytes than this, but they are chiefly of the mononuclear variety, in contrast to the meningococcus meningitis, and, moreover, they do not contain the meningococci. After a provisional diagnosis had been made from the gross appearance, and possibly from the microscopic findings, this fluid was sent to the pathological laboratory for a final bacteriological diagnosis. Sterile fluid usually signifies tuberculous meningitis or hydrocephalus. In some of the cases smears from the nose, mouth, ears, and vagina were also cultured. Frequently a smear roughly obtained from the nasopharynx led to a slight bloody, nasal discharge, which should not be incorrectly interpreted.

The next therapeutic measure was to give the patient a series of doses of calomel, and this was followed throughout the course of the disease by the necessary amount of mild laxatives and enemata. Frequently in the course of a convalescence an exacerbation of temperature denoted a constipated bowel. Its relief would be followed by a normal temperature. Two days later another rise would occur, only to be relieved in the same way. These intermittent rises of temperature might lead one at first to think that the intermittent type of meningitis was present. The hypogastrium was examined to see if the bladder was overdistended. The patient was given milk, or peptonized milk, in sufficient quantities every two or three hours. If necessary, it was administered by gavage. Vomiting was but rarely seen after the first day or two, except when alcohol had been administered. As the disease advanced, a greater variety and quantity of food was given. A proper amount of water was also given at regular intervals. This was especially necessary to replace the large amount lost by the heavy perspiration. If desirable, the nurse was obliged to measure or to estimate, and then record the amount of food retained, the amount of water taken, and the amount of urine voided. I have always believed that the time spent by the nurse in recording on charts and in books the temperature, pulse, and respiration, could be spent to much greater advantage to the patient by charting the measured or estimated amount of food and fluid actually retained.

Having looked after the comfort and nutrition of the patient, the next effort was to supply an abundance of sunshine and warm, fresh air. This was done in the cold months by providing sufficient cubic air space in the ward to each patient, by having numerous steam radiators installed, by having free outside ventilation, aided by electric fans, and by having large window space. In the warmer months the beds were put out of doors under an awning where they remained all day and night, unless the weather became chilly, when they were housed in an adjoining pavilion. All other methods of treatment of the principal disease were discarded after disastrous results.

Complications received appropriate treatment. Conjunctivitis from open eyelids was helped by bichloride of mercury ointment; otitis, by paracentesis and irrigation; bed sores, by relief of pressure and by mercury plaster strapping; vaginitis, by isolation and irrigation; herpes, by the application of styptics; arthritis, by local applications; and bronchitis, by mild and stimulating expectorants. When the patients began to improve, more pillows were allowed and the amount of food was increased. If cod-liver oil was tolerated, this was also added to the diet. Inunctions of the body with cocoa butter or cocoanut oil kept the skin in good condition. Plenty of nonirritating dusting powder, and the free use of bed rings and the frequent change of position, were also essential. When involuntary passages of feces and urine rendered extra protection to the body and bed imperative, it was thought that diapers and obstetric pads were fully as efficacious, and much less harmful to the patient, than the use of rubber sheets covered only by a thin cotton sheet.

A sudden exacerbation of the symptoms during convalescence with the appearance of a turbid spinal fluid denoted a relapse, which was usually much benefited by lumbar puncture and the measures already outlined. If convalescence became prolonged, or if an exacerbation of symptoms occurred, with the spinal fluid clear and profuse, the hydrocephalus that this signified was much more difficult to relieve. Lumbar puncture in hydrocephalus gave occasional temporary help, but frequent tappings did not appear to be of much benefit. Massage and position of the body prevented to some extent the obstinate contractures. Food, air, and sunshine, coupled with time, semed to be the only remedial measures of value in hydrocephalus. Autodrainage by operation was not tried in any of these cases. Many of these cases of hydrocephalus left this hospital apparently cured, and others were sent out to Sea Breeze for future improvement.

Considering the poor results obtained thus far by the more radical measures in the treatment of meningitis, the results obtained in the last two epidemics

at Bellevue Hospital by these simpler rational methods warrants their continued employment until some other treatment shall have been definitely proved elsewhere to be more efficacious.

49 West Fifty-seventh Street.

TWO UNUSUAL EPILEPTIC HISTORIES.

By SMITH ELY JELLIFFE, A.M., M.D., PH. D.,

NEW YORK.

VISITING NEUROLOGIST, CITY HOSPITAL; NEW YORK; CONSULTING NEUROLOGIST, WARD'S ISLAND; ASSISTANT IN NEUROLOGY, VANDERBILT CLINIC, COLUMBIA UNIVERSITY.

Two interesting and even graphic instances of epilepsy have come under my observation within the past year or so. Finding little in literature to correspond to these histories, I have been tempted to give them publicity. I am indebted to Dr. Depeyster Howland, of this city, for the notes of Case I, and to Dr. D. T. Marshall, also of New York, for the history of the second patient. I have presented the bare outline of the history, reserving until a future time the discussion of the etiological and other factors concerning them.

Case I. *Otitis Media, with Hemiplegia; Partial Recovery; Development of Epilepsy; Status Epilepticus; Recovery.*—H. B. O., a girl, aged ten years, gives the following history, which has several points of unusual interest. Her paternal aunt had attacks of epilepsy of the petit mal type for fifteen years. Eventually she recovered and died at the age of sixty-nine. The rest of the family history is negative in every particular.

The patient was perfectly well and in good state of development, walked and talked as well as other children of her age, until November 23, 1895, when she was eighteen months old. She was then taken ill, and complained of pain in her right ear. There was a moderate purulent discharge from the second day; this lasted for several days. Treatment was given by the family physician, who laid the trouble to teething. The pain and local symptoms subsided, and on November 27, she was taken out of bed. It was then seen that she was paralyzed on the left side.

The left side of her face drooped, her left arm was paralyzed, and her left leg was also entirely useless. She was unable to walk, dress herself, or use the left side of her body at all. She had no loss of sensation.

She received daily massage of the leg for six months, with the result that she regained use of the limb, with the exception of flexion of the toes and outward rotation of the leg.

The arm and the left side of her face remained paralyzed; and in her subsequent growth her left arm remained somewhat small, and her left nostril was not so well developed as her right. The facial paralysis gradually improved, so that it was scarcely noticeable.

Her mental development was normal; she talked plainly at two years and read at seven. In arithmetic she was a trifle dull. In her home life she was extremely orderly and neat, everything being put in its proper place and kept there. Her disposition was good; she was not cross and never complained of anything. Of the diseases of childhood she had measles and whooping-cough, both before she was six years old.

She went on normally until about eight years old. Then, in February, 1903, she had a slight convulsion one night and cried out in her sleep. Nothing else abnormal was noticed until March, 1903, when she began to have momentary lapses. She would stand still for a moment, stop her work, play, or speech, and then go on again unconcernedly. After these attacks she often asked what time it was, or where her bed was. It made no difference where she was: at home, visiting, or in school, she asked the same questions. This went on for about one year, during which she had but one chill or convulsion. In the following summer, however, she began to have slight convulsions, at intervals of several weeks, increasing in frequency until she had two or three in a week.

In July, 1903, Dr. E. D. Fisher, of New York, saw her, and made the diagnosis of epilepsy. Her convulsions increased both in number and in severity. There was no aura, no especial order of involvement, nor any particular position of the limbs. The head would droop a bit, the eyes become fixed and staring, the mouth open, and then she would fall or collapse. The arms and legs would develop tonic spasms, even the paralyzed arm being strongly contracted and the fist firmly clenched. She also had slight clonic contractions of the jaw. She had absolutely no cry, and her loss of consciousness was not absolute. Her eyes rolled upward, with pupils sometimes dilated, sometimes normal, but always reacting to light. The duration of the attack was slight, sometimes only a few seconds. At first she was a bit drowsy and tired after the attacks, but would go on with her work. Later she was very much confused and suffered from loss of memory.

In May, 1904, Dr. Berens removed adenoid growths from her pharynx. Immediately following the operation she had four convulsions, but thereafter for two months had none. During the third month they recurred with increased severity. Urine examined on July 22, 1904, showed slight albuminuria and a few granular casts. No sugar, no indican; specific gravity 1.035.

I saw her on July 28, 1904, and confirmed previous diagnosis.

From this time on the attacks became more and more frequent, being as numerous as ten a day. The mental state became much clouded. She called the writer (D. H.) by her sister's name. She was irritable, despondent, said she wanted to die. When asked to get a pair of scissors she would bring a glass of water, and make other similar errors. She forgot her songs, and in her reading she had to go back to her alphabet books. Still she retained her orderly habits and her taste for painting, in which she employed herself by the hour, carefully doing each detail.

On several occasions, when her pulse was taken, during and after the attacks, it first rose to 100 and then fell slowly to 60. The normal is 78. She had no loss of sphincteric control. Still there was no aura nor order of involvement.

On September 9, 1904, she was taken with vomiting, severe and constant, for three days; all food and water was ejected as soon as swallowed. The tongue and teeth were thickly coated. She complained bitterly of pain in the right occipital and parietal region, extending sometimes to the right side of the face.

The writer saw her on September 13. She was in bed, having almost constant tonic convulsions in her legs, and was very dull, but not at all comatose. Pressure on the right side of her head was painful. She had herpes on her lips, and her face was somewhat flushed. The pupils

were moderately dilated and reacted to light. Temperature 99.6,°F. pulse 80–90, full, strong, compressible. One week later she recovered, became brighter, and played about the house. For a few days she had occasional convulsions, and then they ceased and have not returned, nor has she had any psychic attacks. On November 19 the writer examined the patient's ears, and found a small old cicatrix on the right drum membrane. On November 28 she moved her left thumb voluntarily for the first time since infancy, and did so whether her eyes were open or shut, and said she knew it moved.

The general condition has greatly improved, including a gain in weight of twenty pounds. The left arm above the elbow has grown considerably in size, and the tone of the muscles has improved. The facial expression is good, the paralysis having disappeared. Mentally she is a changed child, being as bright as the average child of her age. She is cheerful and takes an active interest in all that she does. Of the period during which she had her convulsions her memory is somewhat poor. Of her attacks she has no knowledge.

Up to the present time, January 31, 1906, she has not had a return of her attacks.

Case II. *Santonin Poisoning; Retinitis; Nephritis; Meningoencephalitis; Permanent Epileptic condition.*—The patient is a girl, the only child of healthy parents. She had always had fair general health, though somewhat nervous, and had always been much constipated.

In the evening of November 5, 1902, after passing a lumbricoid worm, the girl was given one santonin troche, U. S. P. (These troches are supposed to contain about one-half grain santonin.) On the morning of November 6 she was given another troche of santonin and a tablespoonful of castor oil. The castor oil failed to act, and the girl had no movement on November 6.

At seven o'clock on the morning of the next day, November 7, the mother noticed that the girl was unconscious and was in convulsions. How long the little girl had been so the mother did not know, as the patient made no outcry. She was then given a hot mustard bath and the family physician sent for. When he arrived, at 7:30 A.M., November 7, the child was unconscious, and was having a spasm every fifteen minutes. She was given an enema, a short rectal tube two inches long being used. At 11 A.M. a high enema was given, a rectal tube twelve inches long being inserted well up. From 7 A.M., November 7, until 7 A.M., November 8, convulsions occurred at intervals of from fifteen minutes to half an hour.

Beginning at 11:30 A.M. on November 7, chloroform inhalations were resorted to, to abort or relieve the spasms. These inhalations were kept up for twenty-four hours, or until the cessation of respiration during the spasms was so prolonged that it seemed inadvisable to employ it further. After the first twenty-four hours, it was necessary to resort to artificial respiration by the Sylvester method, during the spasms.

The girl recovered consciousness and spoke for the first time about 7 A.M., November 9—forty-eight hours after the onset of the attack.

The treatment of the patient during the stage of unconsciousness was as follows: November 7, 7:30 A.M., enema; 11:30, high enema; beginning at 11:30, chloroform for spasms and ice bag to head; 12 M., eight grains sodium bromide by mouth; 2 P.M., pulse 130, respiration 36, temperature 102° F.; 5 P.M., enema, magnesium sulphate, one ounce in a pint of water; 6 P.M., grs. 1-30 pilocarpine hydrochlorate, hypodermically; 6:30, above dose repeated. This brought on profuse perspiration; 7 P.M., enema, one pint cool water; 9 P.M., pilocarpine, grs. 1-40; 9:30 P.M., codeine, grs. $\frac{1}{8}$ by hypodermic injection; 10:30, 20 grs. sodium bromide, by rectum. November 8, 12:30 A.M., a spinal ice bag was applied, an ice cap having been worn continuously, from the beginning.

From this time on restlessness and irritability were less and the interval between attacks was lengthened. The patient soon began to show signs of exhaustion. When attacks came on the spasm of the respiratory muscles was so long that the patient became very much cyanosed, and artificial respiration had to be resorted to. After the first day the patient could swallow nothing. An enema of one teaspoonful of panopeptone, well diluted, was given every two hours. At 7 A.M., November 9, consciousness returned.

At this time, and for three weeks afterward, the girl was blind, having scarcely any perception of light. No fundus changes could be detected. From November 9, the time of regaining consciousness, until November 25, when her temperature became normal, the girl was exceedingly restless, picking at the bedclothes and at her nose and ears, and keeping up a most exasperating cry most of the time.

Her temperature subsided gradually to normal on November 25, where it remained until December 10, when there began to be a rise of one or two degrees in the evening, possibly due to a nephritis, which had been developing for some time. December 12, temperature 101° F.; December 13, temperature 102°F.; December 14, temperature 103° F.; December 15, 104° F.; December 16, 105° F.

December 16 she passed but eight ounces of urine. She was totally blind, restless; the skin was dry; the urine was loaded with albumin, and the feet were slightly swollen, eyes puffy. Eight grains of theocin was given in four doses.

December 17 she passed thirty ounces of urine, and the temperature fell to 100° F. December 18, evening temperature, 104° F. December 19, began with a daily dose of bitartrate of potash in one pint of lemonade. December 19, temperature 103.5° F. December 20, 99.5° F., 16 ounces of urine. The temperature was 99° F. in the evening and normal in the morning, for one week after that, the amount of urine passed being about twelve to fifteen ounces daily.

Up to December 30, temperature had remained normal and albumen had disappeared entirely from the urine. The girl's sight improved with the fall in temperature, and returned to normal with the disappearance of the fever and the albumen. From this time on till January 20, 1903, there was a steady improvement in health and strength.

On or about the early part of February, the mother noticed that the child would suddenly fall down, or rather *sit* down, and as quickly get up and go on with her play as if nothing had happened. This "sitting down" was a sudden bending of the thighs on the trunk, the knees remaining unbent. There was no cry, no pain, simply a sudden drop and up again, as though the muscles were weak and gave way. These fallings were more frequent during or after ex-

citement. Usually they occurred about six to ten times a day.

In March the girl began falling forward instead of sitting down, so that she frequently fell against the furniture and cut her face. In the early part of April a tight and adherent prepuce was treated, relieving the clitoris. There were no retained secretions.

In the latter part of April, 1903, the attacks ceased, but recommenced late in May or early in June of the same year, when she had from two to ten daily. Sometimes they lasted from half a minute to two (?) minutes. July 8, the attacks ceased for three days. July 11, the attacks recommenced more severely than ever.

On August 12 the physician was holding the child on his lap when she had a severe tonic spasm, very closely resembling an epileptic seizure. This attack continued for one minute, by the clock. The girl was in a sitting posture. Suddenly her head bent forward, her muscles were in a state of strong contraction. She cried out "Mamma, Mamma!" in a weak voice, and seemed to be in great pain. There was no suffusion of the face, no frothing at the mouth, and seemingly no unconsciousness. In a similar attack in the morning, she passed water, and while doing so she cried, "Oh, Mamma, I am peing!" She yawned several times immediately after the attack, and was evidently weak, but she showed no inclination to sleep. Her appetite and general health at present seem good. She needs laxatives to move her bowels.

While in my office at the time of the first consultation, the patient had two of the attacks, which have been characterized as simple muscular weakness. They were typically of this character. The girl, simply and without any loss of consciousness, seemed to sit down, or in one instance seemed more to slip, the floor being a polished floor. In no particular respect could it at this time have been recognized as a *petit mal* attack, notwithstanding the extreme variability of this type of epileptic seizure.

As for the distinct epileptic seizures, which ultimately developed, I have seen but one, and this was a typical. But the family physician has seen a number, and he has had a large experience with epilepsy in children. Thus there is little doubt in my own mind, at least, as to the correct diagnosis.

The further history is of interest. In a letter sent to me by Dr. Marshall, the family physician, he reports improvement:

"August, 1903, had fits, one, two or three times daily. Severe fits two or three times a week. Gave cicutine hydrobromate in full doses. Fits not controlled. September 12, 1903, began giving bromipin ʒ ii, three or four times daily. No appreciable effect. Continued until November 11. November 1 the mother reported that the 'falling spells' had ceased for a week (the dropping on the floor and getting up immediately, as described above), but that the 'real hard spells' were as numerous as ever. November 9 she reported that the child had had no fits during the day, but had had them in bed just before rising in the morning. November 11, 1903, began giving a bromide preparation. November 17, the child's legs were so weak that she staggered and could scarcely walk alone. Stopped the medicine one day, and then began giving it again, and have continued it to date, December 16, 1903. The girl has had no fits of any kind since November 9. The only other treatment beside the sedatives mentioned, has been the continued use, three times daily, of an intestinal antiseptic tablet, containing calcium sulphocarbolate, sodium sulphocarbolate, and zinc sulphocarbolate, each 5 grains; and a laxative composed of aloin, gr. 1-25; strychnine sulphate, gr. 1-500; atropine sulphate, gr. 1-2500; oleoresin of capsicum, gr. 1-500; and emetine, gr. 1-500. Beginning with six of these daily, in a month, the dose was gotten down to one every day or two. Since September 1, 1903, the child has had three treatments a week, with the Marshall vibrator, the machine being applied to the roots of the spinal nerves along the whole length of the spinal column, the treatments lasting about five minutes."

On January 16, 1906, the family physician writes: "In reference to our patient, I would say that on looking over my book I find that the girl has had an attack which from the description, I presume to be epilepsy, about once in two months, since December, 1903. You have her history previous to that Most of these attacks are very mild, and of only momentary duration. She had quite a severe fit on January 1, 1905. I was sent for, and the next day she showed the typical rash of measles, from which she recovered in about a week. In the fall I advised her mother to send her to a kindergarten. I am sure that the diversion and the getting away from her nagging mother has done her good. I expect her to recover fully some day. She has had from five to ten grains of brometone daily for varying periods, whenever she seemed nervous, and along about the first of the month, when an attack might be expected."

As to the interpretations, I leave these to the reader. It is not improbable that in the first patient, the development of an abscess followed the otitis, and pressure or partial destruction caused the paralysis and the latter epileptic phenomena. The recovery, if such it proves to be, may be attributed to the rupture of a secondary cyst and the relief of pressure.

In the second patient, the well-known poisonous symptoms of santonin offer a plausible explanation of the convulsive seizures, the amblyopia and the nephritis. The relation of santonin to naphthalene suggests the type of pathological change that occurred in this child's nervous tissues. An explanation offered in part before a recent meeting of the Brooklyn Neurological Society, needs experimental observation before reaching a final stage as truly satisfactory. This I hope to be able to offer at a later period.

64 West Fifty-Sixth Street.

OPERATIVE TECHNIQUE AND AFTER-TREATMENT FOR MASTOIDITIS WITH EPIDURAL COMPLICATIONS.*

By W. SOHIER BRYANT, A.M., M.D.,

NEW YORK.

The following cases contrasted illustrate three interesting and important points:

First, the use of the front-bent gouge in preference to a mallet-driven instrument;

Second, the use of the modified blood clot in aural surgery;

Third, the question of packing the mastoid wound after exposure of the dura mater.

Case I.—This case was demonstrated at the an-

*Read at the meeting of the Southern Section of the American Laryngological, Rhinological, and Otological Society, at Norfolk, Va., on January 13, 1906.

nual meeting of the American Otological Society in 1904. Three months before the operation the patient suffered from grippe followed by earache. A month later headaches began. At this time there was a seropurulent non-fetid discharge from one ear and very little tenderness behind the ear.

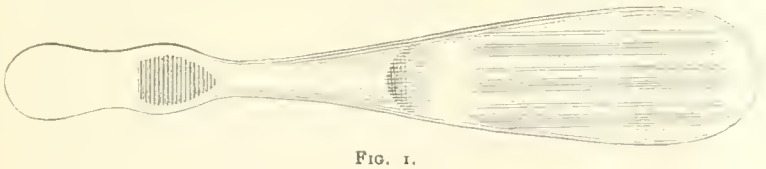

Fig. 1.

There was no edema. On the day previous to the operation the tympanum was filled with inflamed tissues which had been partially removed on several occasions. Pressure showed marked tenderness of the mastoid process, this tenderness being more intense posteriorly. The patient suffered from continuous severe headache. The temperature was 100° F. by mouth; pulse 88; respiration, 20.

Operation.—I commenced the usual mastoid operation under ether anesthesia. An incision convex backward about 2 cm. behind the posterior edge of the meatus was made down to the periosteum, extending from the tip of the mastoid process to the level of the upper attachment of the pinna. With a sharp Bacon's periosteum elevator (Fig. 1) the periosteum was divided in the line of the incision and pushed forward and backward, great care being taken not to lacerate it.

When the bone was well exposed I applied my front-bent gouge (Fig. 2) at the point of election, 2 mm. below and 6 mm. behind the spine of the meatus, and drilled a hole 3 mm. deep, in the bottom of which some cells were opened. (My gouge makes the blows of a mallet unnecessary and it uncovers the sinus without danger of injury.) I then used my gouge to make a trough 8 mm. long through the outer table of the bone, parallel to the anterior border of the mastoid process. Next, with a rongeur, I enlarged the opening in all directions until it was about 15 mm. long and 10 mm. broad. With a curette I then broke down the cells lying within the mastoid process, working chiefly in the direction of the antrum—that is, inward and slightly forward from the point of election and parallel to the posterior wall of the meatus. To make sure no foci of infection remained I removed all the cells. The antrum contained a few drops of pus and some granulations.

The cells about the antrum were filled with granulations which bled readily, particularly in the upper, inner, and back part of the bone cavity. Following this lead, I uncovered a large area of bare dura, the size of a silver dollar. Both the inner and outer tables had been completely eroded and were absent. This exposed dura was covered with granulation tissue. In order to get free access to this area, the

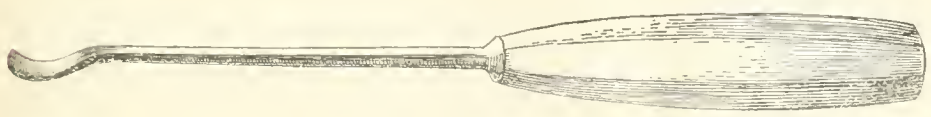

Fig. 2.—Front-bent gouge.

skin wound was enlarged backward by a horizontal incision extending for 2.5 cm. from the center of the first incision. I then removed the whole mastoid process with the rongeur and broke down all the remaining cells with the curette. To make sure that no infected bone could remain I removed, with the rongeur, all the bone surrounding the bare dura, until a border of normal white dura 4 mm. wide extended on all sides (Fig. 3).

The lateral sinus appeared traversing the denuded dura, and I removed, with the rongeur, the outer third of the posterior wall of the meatus to allow the pinna to sink inward to obviate any possible deformity or pitting behind the auricle. I washed the whole wound carefully with normal salt solution to refresh the injured tissue and to clean off the loose, infected material and dust which might be in the wound. I inserted a rolled-up strip of one-half inch gauze for a drain which extended from the bare dura to the center of the skin incision. To promote union, I then put the periosteal and skin flaps in apposition. No sutures appeared to be necessary to hold them there. I packed the meatus with plain gauze to promote drainage and to prevent the collapse of the canal. To encourage the flow of serum from the wound on account of its antiseptic value, I applied a gauze dressing moistened with normal salt solution.

Convalescence.—On the two days following the operation the patient was troubled with a stiff neck, but had no pain. The outside dressings were renewed twice because they were soaked. On the first

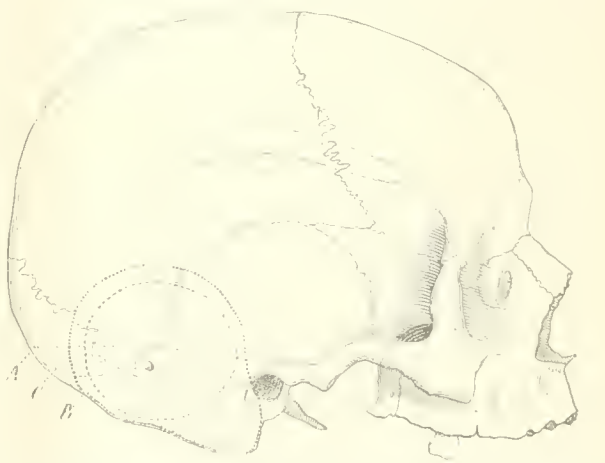

Fig. 3.—A diagram of the skull showing the course of the sinus in line *A*, and the outline of eroded bone in line *C*, and the edge of the bone excavation in line *B*.

day the temperature was 100°, the highest point reached during the convalescence. I removed the gauze strip from the wound, and the packing from the canal. The wound was dusted with boric acid and the packing replaced in the canal. On the eighth day the patient's temperature was 98°, pulse 84, and respiration 20. On the fifteenth day the external auditory canal was dry and in good condition and the drum membrane healed. The posterior external wound was completely healed except a very small sinus at the center of the incision which led into the antrum and discharged a little turbid, non-fetid fluid. On the nineteenth day the acumeter was heard sixteen inches. On the twenty-first day the postaural wound was dry, healed, and epidermatized. A small epidermatized pit was all that was left of the small sinus at the center of the incision. On the twenty-third day the hearing was good. The wound remained healed and solid, and the patient had gone back to laborious work. No pain, tinnitus,

nor vertigo occurred after the operation. The resulting scar was very small and the outer surface of the scalp showed a very slight unevenness (Chart 1).

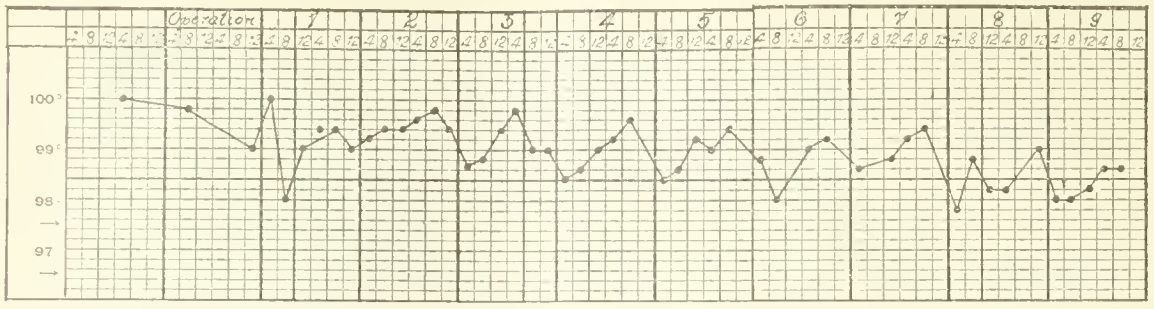

Chart 1.—Temperature curve in Case I.

Case II.—The second patient was a heavy man, 36 years of age. Four months previous to the operation he had had an attack of the grippe, followed in four days by great pain and swelling of the face and region of the ears, with discharge. When seen, two days before the operation, a pure culture of streptococci was made from the discharge. There was no external appearance of inflammation, and the tenderness over the mastoid was not marked. The headaches were severe.

Operation.—I commenced a mastoid operation on the right ear under chloroform anesthesia and made a skin and periosteal flap like the one in the previous case. The mastoid cortex appeared normal and was rather thin. I perforated it by the same method as in Case I. The process was large and cellular. The cells were small and filled with pus and granulations. The trabeculæ were friable and were easily removed with a curette. I uncovered a perforation opening into the digastric fossa, but little or no pus had escaped. The inner table of the bone covering the knee and the descending part of the sigmoid sinus was crumbling. I easily removed it with a curette. The area of osteomyelitis extended downward, backward, and inward along the occipital bone nearly to the foramen magnum and the bulb of the jugular. The surface of the dura beneath this softened area was covered with granulations. As in Case I, I enlarged the skin incision backward and removed the surrounding bone with a rongeur in order to expose a healthy border of dura mater (Fig. 4).

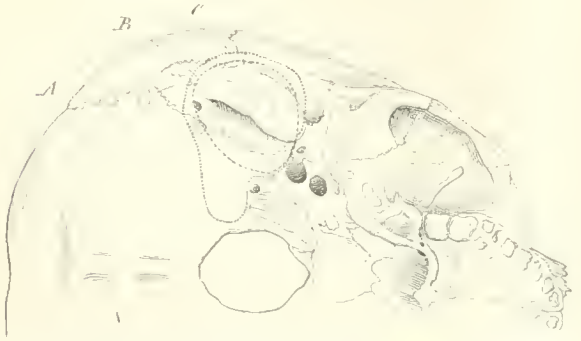

Fig. 4.—A diagram of the skull showing a three-quarter view of the base. The outline of the sinus is line *A*. The outline of the granulating dura is line *B*. The outline of the dura uncovered by the operation is line *C*.

When I accidentally detached the emissary vein from the sinus there was free bleeding. I readily stopped it with a wad of iodoform gauze. With the curette I removed the whole mastoid process, which was exceedingly soft, and extended the osseous cavity upward through harder bone which contained granulations in numerous small cells. I separated the periosteum from the upper wall of the canal and the outer half of the posterior wall with a special periosteal elevator devised for the purpose with a small, straight blade (Fig. 5). I used a narrow strip of flexible copper sheet to protect this periosteal epithelium from injury during the removal of these osseous walls and the cleaning of the tympanum, because of the value of this epithelium in the final process of epidermatization. I removed the hanging wall of the meatus, thus opening the attic by the removal of its external wall, and extended the cavity to include some zigomatic cells which were also filled with granulations. I did all this bone

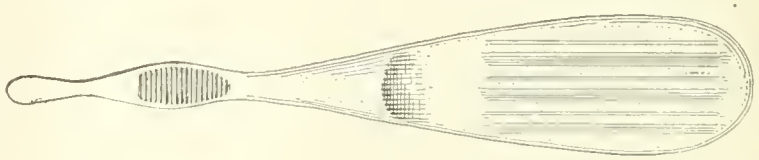

Fig. 5.

work with chisel and mallet. I removed the drum membrane, major ossicles, and as much mucous membrane as possible, without injuring the facial nerve or stapes, using for this purpose a small ring curette. I then washed thoroughly the whole wound and ear with salt solution, and slit the membranous meatus posteriorly along its inner third and packed it with iodoform gauze to separate its cut edges to assist in the epidermatization of the tympanic cavity. I packed the wound lightly with iodoform gauze because there was a question as to whether all the infected tissue had been sufficiently removed, and finally applied a wet dressing covered with rubber tissue.

Convalescence.—Three days after the operation when the dressing was changed it was very adherent in the wound and caused considerable oozing on its removal. There was no sign of infection. The gauze at the emissary vein was loosened and bleeding followed. On the fourth day the meatus was dry. All the dressing on the posterior wound was stained and the gauze in the wound was adherent. The plug in the emissary was removed with little bleeding. Gentle packing with iodoform gauze was applied in the wound, and plain gauze in the meatus. On the ninth day the gauze in the wound was moist and not adherent. There was no sign of infection. The wound was closing well from below and granulating evenly. Boric acid and a very little gauze were put in. On the tenth day the wound was moist and was filling up well. It was dressed with boric acid. No packing was used except in the meatus. On the nineteenth day the granulations were shrinking and

the wound filling up. Boric acid was used in the meatus and the posterior wound, and a strip of very narrow gauze placed in the post-aural opening. No gauze was put in the meatus. The bandage was adjusted to support the ear, which had a tendency to droop. On the twentieth day boric acid was applied. No packing was put in the wound. On the twenty-first day the wound was all cicatrized except an area the size of the end of a lead pencil. On the twenty-second day the middle ear was entirely epidermatized and dry. On the thirty-second day the meatus was opening well and the posterior wound wholly cicatrized. A slight deformity is noticeable, owing to the pit at the center of the incision (Chart 2). The patient complained of headache for the first three days after the operation, besides appearing a little dull.

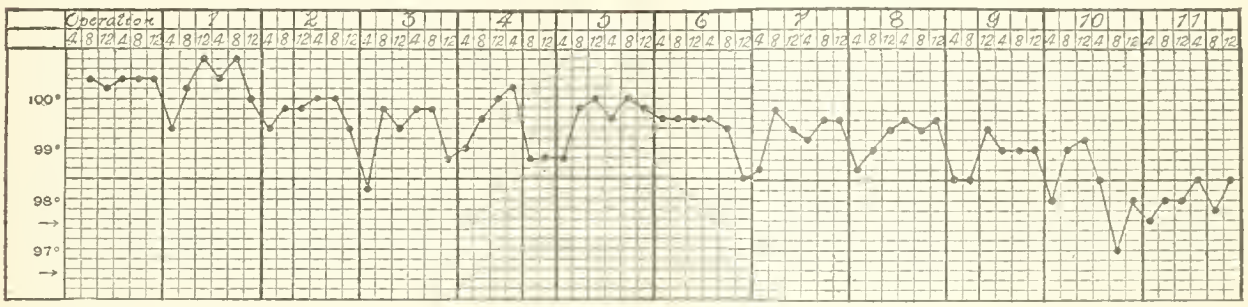

CHART 2.—Temperature curve in Case II.

Recapitulation.—My front-bent gouge was very useful in perforating the mastoid cortex, after which the rongeur and the curette did all the bone work, except in Case II, where the chisel and the mallet were used for the epitympanic work. The first steps of the operations were the same as in uncomplicated cases of mastoiditis. As the work proceeded, the wounds were enlarged sufficiently to uncover all the affected dura, and bone was removed until healthy dura surrounding the diseased area was exposed.

After all the inflamed dura mater had been uncovered and all the affected bone had been removed, the wound in Case I was closed without sutures, and the wound in Case II was packed and left open. The unpacked wound collapsed and partially filled with a blood clot, and thus reduced the size of the cavity which had to granulate up finally and cicatrize.

In neither case were there any complications in the convalescence due to the exposure of a large area of dura mater. In Case I the convalescence was very short and the deformity reduced to a nearly imperceptible scar and a scarcely perceptible pitting. In Case II, although the wound was not infected, the convalescence was much more prolonged, and the scar larger and the pitting deeper.

Conclusions.—1. The best results are obtained (*a*) By the use of the front-bent gouge instead of chisels or other gouges requiring the mallet, because it allows the convalescence to begin more quickly.

(*b*) By closing the mastoid wound and allowing it to collapse and partially fill with a blood clot to promote union by first intention, thus shortening the convalescence.

(*c*) By allowing the anterior flap of the wound holding the pinna to fall inward and backward and lie on the posterior and inner wall of the wound because this improves the post-aural cosmetic effect.

(*d*) By avoidance of packing which causes the formation of a large cavity requiring a long time to granulate up.

2. The exposure of the dura mater is a complication of no special importance.

ULCUS RODENS (MOOREN).*

By H. H. SEABROOK, M.D.,
NEW YORK.
SURGEON TO THE NEW YORK EYE AND EAR INFIRMARY.

THIS brief report does not attempt to avoid certain characteristics made illustrious by Homer and Kipling. As much as was wanted was taken from the classical paper of E. Nettleship, published in the Transactions of the Ophthalmological Society of the United Kingdom for 1902, page 103. In addition to the seventy-four cases accepted by Nettleship there are ten considered herein; one each by Taylor and Fisher and two by Lawford in the same volume as Nettleship's paper, two reported by J. Asayama at the Japan Ophthalmological Congress of 1902, two by Wanner and one by Distler in the *Ophthalmologische Klinik* for 1905, and one shown here to-night.

Bowman published the history of a case of this disease in 1849, and Mackenzie was evidently acquainted with it in 1854, but the credit of describing it as a distinct species is due to Mooren, who published cases in 1867 and 1873. Steinheim published the eleventh case and first cure in 1877. This cure was obtained after two-thirds of the cornea had been lost, by cauterization with pure carbolic acid.

The first microscopical examination was made by Lawford from an eye excised at Moorefields by Tweedy in 1889. The case was supposed to be one of epithelioma at the time, and this diagnosis has been not infrequent in cases of the rodent ulcer of Mooren, although most of the six eyes (from Tweedy to Asayama) which were enucleated, were removed because of unfavorable conditions, in cases known to be rodent ulcer of the type under consideration.

According to Mooren this disease occurs about once in 40,000 eye diseases; Janny puts the proportion as 1 in 66,000, while Asayama claims in Japan 4 cases among 6,780 of eye diseases. It starts obscurely, and may consist at first of an apparent infiltration or abrasion near the margin of the cornea, from which spreading takes place marginally and centrally. Unless checked the process invades the whole corneal area, leaving the cornea thinned, scarred, and cloudy. Sometimes a second ulcer forms distinct from the first,

*Notes read upon the presentation of a case of Mooren's ulcer to the Lenox Medical and Surgical Society, December 23, 1905.

and the two eventually join. Iritis is common, but hypopyon and perforation are rare. The greatest advancement takes place at a depth of about one-third the thickness of the cornea, the anterior necrosed layers forming an overhanging edge which, with the cloudy epithelium, gives the characteristic gray line at the ulcerating border, where advancement takes place; the old portion of the ulcer remains more or less healed and partly filled with vascularized granulation tissue covered with epithelium. The disease may be stationary or apparently improving for days, weeks, or even occasionally for months, then, without apparent reason again advance. Pain, congestion, photophobia, and lacrymation vary, being very severe when the ulcer is extending, and usually ceasing when the whole cornea has been involved. The duration is from two months to over a year, from four to twelve months being the usual time. In thirty-six out of forty-six cases it began between November and May. It occurred in one child of less than three years of age; in all other cases in adults, about one-fourth under forty years, one-fourth over sixty, nearly one-half from forty to sixty. Both eyes are attacked in more than one-fourth of the cases, the interval between the first and second eye being variable, but the process in the two being remarkably similar in primary situation, virulence, and course.

The cause is unknown. Bacteriological examination has been practically negative, but one unconvincing attempt having been made to describe a specific bacillus (E. Andrade, "Ulcus Rodens della Cornea con rispetto di uno speciale bacillo," *Annali di Oftalmologia*, 1900). The results of examinations of excised eyes have been sufficiently indicated in the description of the ulcer previously given.

It is unnecessary to discuss many forms of treatment. Carbolic acid has not succeeded in checking the process in most cases in which it has been used. Chlorine water and subconjunctival injections of mercuric perchloride and silver nitrate have a similar record. In 1899 Koller mentioned that a case of double rodent ulcer had just cleared under treatment with tincture of iodine after the galvanocautery had failed to check the trouble; this was incidental in a paper concerning iodine treatment of corneal ulcers. In my case the ulcer cleared beautifully under tincture of iodine and seemed certain to heal, but relapsed later, when the iodine proved painful, irritating, and inefficient. In three other reported cases tincture of iodine was a failure. The most widespread treatment has been the galvanocautery, and upon reviewing reports of this, one does not wonder that Mr. Nettleship should refer to it in one place as a success and a little later as a failure, both opinions somewhat qualified. More cases are reported cured than not by this method in the sense of the process being stopped at least temporarily, but there would seem to have been decidedly more failures, which were of course certain, than properly substantiated permanent cures. Furthermore, protest has been made, in which I join, against a method being used in well advanced rodent ulcer which, because of the deep dense cicatrix, results in a worse eye, as regards both appearance and vision, than if the disease had been allowed to take its course. The same objections may be urged, as regards results, against the one apparently successful method of treatment. Two cases in which the conjunctiva became adherent to the floor of the ulcer underwent spontaneous cure. Two others were cured by transplantation of a conjunctival flap upon the ulcer. To these Distler's recent case (*loc. cit.*) may be added. Subsequent to an apparent cure, lasting two months after the use of the galvanocautery there was a relapse. Transplantation of the conjunctiva stopped the process of inflammation and degeneration for one year. Ulceration then began again with some virulence, when the old flap was removed and a new one applied, with the result that further ulceration was checked during the six months the case remained under observation.

We have here a perfectly healthy man, an actor, thirty-seven years old, with rodent ulcer of over eighteen months' standing, which has so far involved all of the cornea except a small patch outward. After treatment of various sorts, ending with tincture of iodine, had failed, the edge of the ulcer had reached the margin of the pupil. Pure carbolic acid seemed to check it at this point, except for occasional relapses at the upper portion for several months, when the anterior layers of the cornea began to break down along the whole edge of the ulcer except that directed toward the corneal limbus. Carbolic acid shortened the exacerbations and ameliorated the symptoms and was continued; gray lines extending from the point of application into the lymph channels of the cornea sometimes under the whole breadth of clear epithelium, hinted a reason why cauterization failed to stop the extension of the ulcer. Dionin in 10 per cent. solution has been used and vision already (20/c.c.) is equal to the best primary vision so far definitely recorded (Asayama, *loc. cit.*). The eye promises to have a fair appearance and useful vision in the course of time.

In the corneal rodent ulcer of Mooren we have a remarkable process. It attacks the parenchyma of the cornea with the utmost malignancy, but is easily resisted by the membrane of Descemet posteriorly; and although there is some swelling outside the limbus, the episcleral tissue at the margin of the cornea being infiltrated with small round cells, ulceration, which regularly occurs in this situation in epithelioma of the eyeball, has occurred here in only one case of rodent ulcer (Gifford's). In that case the galvanocautery cured the conjunctival ulceration with one application, and the corneal ulceration healed, although it had previously resisted cauterization.

The writer would suggest some form of protozoon as a probable cause of the rodent ulcer of Mooren. If this supposition were correct it would be difficult to prove, since it is unlikely that enough cases will arise in the future in which sufficient ocular tissue could be properly sacrificed for convincing investigation.

118 East Seventy-second Street.

Action of the X-Rays on the Virus of Rabies.—Alfonso Calabrese tells us that many bacteria in solutions are killed by the action of the Roentgen rays. He has instituted experiments to determine whether this action is effective against the cause of rabies as contained in the virus of rabies. The *x*-rays were made to act on bits of nerve tissue, emulsion of the same, and directly on the eyes of rabbits infected with rabies through the anterior chamber. In these cases the action of the rays, prolonged for from two hours to eight days, failed to save the rabbits from rabies. The author is convinced that there is no hope of being able to prevent or cure rabies by means of the *x*-rays, and that there is no apparent effect from them on the virus.—*La Riforma Medica.*

MEDICAL RECORD.

A Weekly Journal of Medicine and Surgery.

WM. WOOD & CO., 51 FIFTH AVENUE.

New York, March 31, 1906.

RELAPSING FEVER.

ALTHOUGH relapsing fever was the first infectious disease in which the parasite was demonstrated in the blood, no very notable facts in regard to the etiology of the malady have been discovered since Obermeier in 1873 described the spirillum or spirochete which bears his name. In the course of several severe epidemics at about that time it was learned that uncleanliness and close personal contact apparently had something to do with the transmission of the disease, for it was most common in vagabonds and tramps, railway laborers who lived huddled together in barracks, and prisoners in large penal institutions. Several Russian observers, notably Metchnikoff, who inoculated himself, showed that the blood of a patient injected into a healthy person produced the disease, but the spirochetes rapidly died outside of the body; and even Tictin's observation that the stomach contents of bedbugs that had fed on relapsing fever patients contained spirochetes was not very remarkable, since it was only natural that this should be the case, and did not clear up the question of transmission. The infrequency of relapsing fever of late years has also rendered research unfruitful, so that the matter has been resting in a rather unsatisfactory state.

Strangely enough, it is out of Darkest Africa that light has been shed on this obscure subject. One of the latest publications relating to the matter is that of Robert Koch, who, starting with the comparatively recent observation that a type of fever occurring in German East Africa and previously regarded as malarial was really due to an organism nearly or quite identical with that of Obermeier, a year ago undertook the study of the local conditions. At that time practically every white man who traveled along the caravan route which runs from Daressalam into the interior, at Tabora branching so as to reach Victoria Nyanza and Lake Tanganyika, contracted the disease. Koch took the long journey in person, at times making side trips which led to regions which he says even the Arab traders had never visited, and now presents evidence that appears to confirm the suppositions of other observers regarding the intermediate host of the spirochete. In his description of the investigation (*Berliner klinische Wochenschrift*, February 12, 1906) he says that thanks, perhaps, to the experience in dissecting and preparing ticks gained in his previous work on the South African cattle fevers, he succeeded in assuring himself that a certain tick, *Ornithodorus monbata*, which he says is the only tick that feeds exclusively on human blood, frequently was infected with the typical spirochetes, and that these were most numerous on the ovaries. Further observations revealed the fact that a large proportion of the eggs laid by an infected female also contained spirochetes, and monkeys invariably developed relapsing fever if exposed to the bites of the newly-hatched insects. The ornithodorus is found in the soil of the dirt floor of practically every negro hut, and also in the shelter huts erected all along the caravan route. The insect is nocturnal in its habits and emerges to feed on sleeping travelers, reburying itself as soon as satisfied. Although it was not possible to obtain exact evidence on this point, the assumption is that the spirochetes of the young insects are present about the salivary glands or suctorial apparatus. Quinine and other drugs are powerless as curative agents or as prophylactics, but it is easy to avoid the disease by never sleeping in a native hut, and Koch's party escaped in this way. The natives appear to become immune through being infected in childhood, but coast natives show the same susceptibility as whites when they go into the interior. In order to explain the constant infection of mature ticks that appears to take place, Koch suggests two possibilities. One is that apparently healthy individuals, perhaps children, who have had the disease and recovered may still have spirochetes in their blood, and the other is that rats and mice may serve as a third host for the spirochete. In fact, it was found possible to infect both of these animals with the microorganisms. Still another possibility is that there may be cases of the disease so mild that they escape recognition, and these can keep up the supply of microparasites for infection of the ticks.

Koch's observations are of much interest and value, but he does not mention in his communication the fact that in July, 1905, Ronald Ross read a paper by Todd and Dutton—the latter of whom died in Africa of spirillum fever contracted in the course of his investigations—before the section on tropical disease of the British Medical Association, in which these observers stated that the organism causing the African tick fever was probably the spirillum of Obermeier and that the transmission was effected by the *Ornithodorus monbata*, some developmental process probably being carried on in the tick. Norris recently discussed the subject before the New York Pathological Society, and in his paper, reproduced in the Proceedings of that society for January, 1906, suggests that some of the obscure febrile affections observed in this city in sailors coming from tropical ports may possibly be instances of spirillum infection.

While it is a matter of satisfaction to have our knowledge of the etiology of this disease placed on a firmer basis, it is irritating to feel that, given so clearly demonstrable a parasite as the spirochete, we are still unable to offer the patient a specific remedy. Possibly further development along the lines advocated by Ehrlich, who discovered a chemical substance—trypan red—which has a definite, although not altogether adequate specific effect on trypanosomes, may lead to the discovery of a specific for relapsing fever also. Perhaps when Koch returns from his next African expedition, which is to start on April 16 and last for a year and a half, he will have progress to announce in this direction also.

THE NAVAL MEDICAL SERVICE.

In about two months the medical schools will turn out several hundred new physicians who will have to decide upon their life work. A young man who has made up his mind to study medicine thinks at the outset that he has chosen his career, and that there is nothing more for him to do but to bend his energies to the securing of an education in the principles of medicine and then to apply these principles in practice. But as his time for graduation approaches he finds that the choice of a career still lies before him. Shall he become a general practitioner or family physician, the breed of which is not extinct and never will be; shall he take up surgery or gradually work into one of the specialities; shall he go into life insurance or take up literary or laboratory work, all of which, in the larger cities, have developed into specialities incompatible with actual practice; or shall he enter one of the public services—the Army or Navy or Marine Hospital Service? These are questions which must be decided and decided definitely before graduation, or certainly before the completion of the post-graduate hospital service, which every medical graduate should take if he would make himself an accomplished p[illegible].

With no desire to influence the recent graduate against his inclinations, but simply to point out an opening for an honorable career to the young man with ambition and with a bent toward the sea, the Medical Record would call attention to the opportunities now presented in the naval service. For many years the navy had few attractions to offer to the medical man. His rank in entering the service was low, and he was compelled to mess with the midshipmen just out of Annapolis and several years younger than himself. This and other humiliations under which the newly-appointed assistant surgeon in the navy had to labor were such that few men of spirit were willing to submit to them. But that condition no longer exists. Now an assistant surgeon's rank is that of a junior lieutenant, which is equivalent to first lieutenant, cavalry, in the army. He messes with the other officers and is far above the middy, who has to wait nine years to attain that rank. Moreover, he may become a passed assistant surgeon, with increased rank and pay, in less than a year after entering the service, if he passes the examinations, whereas formerly it was necessary to pass through a probation period of three full years before attaining that rank.

There are advantages and disadvantges in the service, and the young graduate should weigh them carefully before deciding to enter it. The advantages are that the naval surgeon has an assured income from the day he enters the service, and one which increases with each year of service; he has opportunities for seeing the world that few men dependent upon their practice for a living ever obtain; he has an honorable position and the companionship of gentlemen which he might or might not lack in civil practice; and he has the opportunity to study tropical and other diseases which the routine of family practice in an interior town would never bring to him; and, of course, one who loves the sea would get his fill. On the other hand the sea surgeon is seriously hampered in the enjoyment of family life; he may be married, but his duties will entail long and trying separation from wife and children. If he thinks that he is to be stationed for a long period in some foreign or domestic port, his family can follow him, and he can visit them occasionally when he gets leave; but they may be just settled in Yokohama, or Manila, or Nice when he is ordered back to New York, or San Francisco, or to the West Indies, and then comes a long separation and the expense of the voyage back of the family to the new station. That is the disadvantage of the naval service—and a serious one it is to many who would otherwise embrace the life with avidity.

The navy is no place for the lazy man, but for the one who has high ideals of work and is ambitious it offers temptations. Preferment comes only after examination, and, although the service is in dire need, there is no relaxation in the standard. The examinations are stiff, and they must be passed creditably by all who would advance to a higher rank in the service. But there is time enough for study, and opportunity is offered for original investigation, and no man who works need fear the examination. The examination for admission to the service is practically no more difficult than many of the State examinations for license to practice. The pay in the navy is not large, but it is sure, and any surgeon who is invalided in the service is assured of an income which will support him for the rest of his life.

THE POPULARITY OF CESAREAN SECTION.

The development of a more perfect operative technique and the observance of the most rigid asepsis have been the means of lowering the mortality for cesarean section from over fifty to less than ten per cent. The favorable aspect presented by these figures has naturally led to an increase in the number of cases in which the procedure has been employed, and the operation from having formerly been regarded as a most serious undertaking has now attained a vogue, which, unless checked, may ultimately defeat the ends for which the operation was originally proposed. A plea for greater care in choosing this procedure as a way out of many difficulties which might be better dealt with otherwise is contained in a recent article by C. B. Reed, published in *Surgery, Gynecology, and Obstetrics,* for January, 1906, in which he raises a warning voice against the too frequent performance of the operation. Much of this popular desire has undoubtedly been inspired by the favorable statistics which have emanated from the hospitals, where of course the outcome is governed by a series of advantageous factors and conditions which cannot very well be repeated in ordinary practice nor by the ordinary practitioner. Among these factors may be mentioned the practice of a rigid asepsis and antisepsis, not only in reference to operator and patient, but in the presence of his assistants and the environment. Care and skill on the part of the operator and the nurse who takes care of the patient, and a knowledge of, and the means for treating complications and emergencies can rarely be found outside of a properly equipped hospital in the larger cities. Where these essentials cannot be attained, it is incumbent upon the attending

physician in any given case, according to Reed, to choose an operation which is coupled with less danger to the mother and which can be carried out with greater chances of success as regards her life at least.

Dr. Reed suggests that a procedure which is eminently adapted to the conditions may be looked for in perforation. This has a much lower mortality in general practice than cesarean section: it is moreover a comparatively bloodless operation, and the mutilated child can usually be readilly enough extracted by the natural passages, while in cesarean section the large abdominal and uterine wounds offer an opportunity for a very small amount of septic material to become extremely dangerous. The preparation and the technique for perforation can be carried out even in the poorest surroundings, elements which do not apply to the performance of a cesarean section. The after-treatment does not differ materially from that of the ordinary parturient case, and no special nursing arrangements are necessary.

In this discussion the welfare of the mother has been made the principal, if not the sole aim of treatment, and in support of this claim may be quoted the famous maxim of Simpson, that the safety of the mother is the supreme law. Reed also argues that the mother is of great economic value to the State, while probably not more than two-thirds of babies born living survive their fourth year, therefore the latter, from the civil standpoint at least, has a much smaller claim to life than the mother, unless she is hoplessly diseased. These statements apply, of course, more particularly in country practice and in "relative indications" only, but where the facilities and the skill are at hand, the operation of casarean section may and should entirely supplant perforation as an obstetrical procedure.

The Fate of Paraffin in the Tissues.

Since its introduction by Gersuny, scarcely more than five years ago, the injection of melted paraffin into the tissues for various plastic purposes has been quite extensively employed. A great deal has been written regarding its manifold advantages, but as yet we know comparatively little of the behavior of this substance after its introduction into the tissues. A better knowledge of this process is of great importance for practical as well as for theoretical reasons. We know that its introduction is not always well borne, and sometimes the injected material, together with the surrounding tissues, may be entirely extruded. An interesting contribution to the question of what becomes of the paraffin which remains *in situ* is made by I. Kirschner (*Virchow's Archiv*, vol. 182), who was able to examine a number of specimens taken from patients in whom the injected areas had been removed by operation for various reasons. Kirschner found that a distinction had to be drawn between the soft and hard varieties of paraffin. When the former had been employed, histological examination of the excised tissues showed that the material was completely absorbed; and even if this was accompanied by a gradual substitution of connective tissue corresponding roughly to a reparative process, there was always a danger present that this newly organized tissue might undergo contraction later on. It was also found that the injections were not well tolerated in those localities where the skin was quite firmly united to the underlying bony structure by dense connective tissue, as on the face. Unfortunately, these are the situations where the procedure is most frequently employed.

The encapsulation or imbedding of the hard varieties of paraffin has rarely ever been doubted. Kirschner's observations show, however, that in these instances we are dealing with a foreign body, traversed by a network, whose individual strands are made up of connective tissue and giant cells, the latter surrounding directly the small remnants of paraffin. Although commonly designated as "hard," it was found that the irregular crystalline structure of the latter readily permitted the invasion of the cellular elements, until the entire mass was finely subdivided and absorbed by the action of both leucocytes and giant cells.

If we apply the information gained from these observations to therapeutics it is quite apparent that neither variety of paraffin can be included among that group of foreign substances which may remain permanently imbedded in the tissues or become encapsulated and separated from the surrounding parts. The procedure in question has been employed in the restoration of anatomical defects arising from various causes, and in other conditions, and it has been hailed as an ideal therapeutic resource. The results obtained from studies such as those here referred to will undoubtedly lead to further trials in the production of a medium of similar character, but without the disadvantages which have been shown to be connected with simple paraffin, which may be used to meet the same indications.

A Law Against Substitution.

A bill has been introduced by the Hon. Alfred R. Page into the New York Senate amending the Penal Code so as to protect the physician against the injury done him and his patients by the dishonest pharmacist. Most druggists who aspire to any higher calling than the sale of soda water, cigars, and patent medicines are, we believe, honest, and can be trusted to compound the physician's prescription exactly according to directions, but there are some black sheep, and it is to prevent such from tampering with prescriptions, substituting inert or injurious substances for the more costly drugs called for by the writer of the formula, that this excellent bill is framed. The act provides that anyone who, in filling a prescription, departs from the letter of the instructions in regard to the quantity or quality of the drugs, or who substitutes any drug or drugs for one or more called for by the writer of the prescription, shall be guilty of a misdemeanor and may be punished therefor. For a second offense this punishment shall be imprisonment for a term of from ten days to one year and a fine of from ten to five hundred dollars. A third conviction disqualifies the offender from practising pharmacy. The act applies only to the compounding of physicians' prescriptions, and expressly permits the druggist to recommend the purchase of some other article than the one ordered (not in a prescription) and to sell the same with the knowledge and consent of the purchaser. The provisions of the act are therefore not hard and are designed only to prevent fraudulent substitution. The bill is the same as one passed at a former session of the Legislature, but vetoed by Governor Odell. It should be passed again and it is believed that, if it is, it will receive Governor Higgin's sanction.

News of the Week.

"American Medicine" to be Issued Monthly.—In the current issue of *American Medicine* announcement is made that the journal will in future be published monthly instead of weekly. We are sorry to lose our contemporary from the ranks of the weekly journals, for it has ever stood for the best in professional literature. In the proposed change we are assured that there will be no lowering of scientific, professional, or literary standards. We cordially wish for our contemporary in its new form all the success which deserved professional sympathy and support will surely bring it.

Red Cross Society.—With the idea of rendering it possible to give prompt physical and financial aid in public disasters, the New York State Branch of the Red Cross Society has announced its intention of extending its organization to every county and large city in the State. It is planned to create a membership of persons who will contribute $1 a year or a life fee of $25, and of others who will volunteer their services in times of calamity.

American Urological Association.—A meeting will be held on Tuesday, April 3, 1906, at 7.30 P.M., at the New York Athletic Club. The paper of the evening will be "Surgery of the Ureter," by Dr. Eugene Fuller. The paper will be discussed by Drs. Douglas H. Stewart, Louis Heitzmann, W. E. Deeks, Wm. K. Otis, Howard A. Kelly, Winfield Ayres, and Carl Beck. The president is Dr. Ferd. C. Valentine of New York and the secretary, Dr. Hugh Cabot, 1 Marlborough Street, Boston.

The Osteopathic Bill.—The Medical Society of the County of New York has issued the following: "The attention of the members of the Medical Society is called to Senate Bill 293 and Assembly Bill 627, entitled: 'An act regulating the practice of Osteopathy in the State of New York.' This act provides for the licensing of all Osteopaths who are now in the State to practise medicine without any examination, and establishes for those who subsequently come into the State to practise Osteopathy, a lower standard of education than is now required of other practitioners of medicine. Will you kindly write to your representative in both Senate and Assembly expressing your opposition to this bill, and urging the necessity of compelling all who practise medicine in any form to comply with the present Medical Laws? Your active and immediate cooperation is urged to defeat this attempt to lower the standard of medical education, and to evade the requirements of the laws governing the practice of medicine in this State."

To Prevent Transfer of Patients.—A bill which has been introduced at Albany to prevent the transfer of patients from one hospital to another provides that the person ordering such a removal is punishable by a fine of $5,000, or five years' imprisonment. No exceptions are made in the case of infectious diseases or other cases of necessity.

Seaside Park Bill.—The bill providing for the establishment of a seaside colony for New York City's sick poor has been modified by the Assembly Cities Committee to such an extent that its usefulness has been greatly impaired. The appropriation for the purpose has been cut down from $2,500,000 to $1,500,000, an amount which it is stated will be insufficient to acquire even the site necessary for the project.

Charities Federation.—The committee appointed by Comptroller Metz to consider the federation of the private charities to whose support the city contributes, has approved the general plan proposed and has appointed a subcommittee to settle details. The idea is to form a federation with a central board of administration for the study of statistics and the exchange of ideas. Public conferences will also be held at stated intervals. It is expected that in this way the services rendered to the city will be made more efficient.

The Health of New York City's School Children.—According to a report made public by Health Commissioner Darlington, since the reorganization of the system of medical school inspection of the Board of Health on March 29, 1905, the inspectors have examined 55,332 children, and have reported 18,182 cases of defective teeth, 16,394 cases of defective vision, and 6,182 cases of defective nasal breathing. Treatment was necessary in 33,551 cases. The conditions most frequently encountered were enlarged anterior cervical glands, visual defects, and imperfect teeth, of each of which more than 14,000 cases were recorded. During the last year 88,964 visits were made to the schools by medical inspectors, and 18,844 children were excluded for contagious disease. Of this latter number, 8,833 were for eye diseases, 4,692 for pediculosis, 2,018 for skin diseases, 312 for measles, and 74 for diphtheria. During 1903, 65,294 children were excluded, and during 1904, 25,369. Much importance is attached to the work of the school nurses, through which many children that would formerly have been excluded are enabled to continue in attendance.

To Study Physically Deficient Children.—The president of the Board of Education has appointed a committee of three commissioners to study the present facilities for the education of the blind, crippled, and otherwise physically defective children in this city, with a view to having the educational authorities assume their care.

Literature of Quack Concerns Excluded from the Mails.—Postmaster-General Cortelyou, as the result of investigations carried out by inspectors of the Postoffice Department, has issued orders to the postmasters of the New York and Brooklyn offices to refuse admission to the mails to the advertisements of fifty-two bogus medical concerns in New York City and to refuse delivery of mail matter to any address where such business is conducted. Like action has already been taken against some thirty similar enterprises in Boston and thirteen in Philadelphia.

Magic Boots Maker Held.—The manufacturer and the vendor of the so-called "magic boots," which were sold to people of all sorts and conditions at exorbitant prices under the pretense that they contained curative principles of great value for almost all diseases, have been held in $1,000 and $500 bail respectively for the grand jury. The former is accused of grand larceny, and the latter of practising medicine without a license. Another unlicensed practitioner has also been arrested, whose method was to delude poor women on the East Side into the belief that he could relieve them of sterility, and who apparently succeeded in finding a very large number of victims.

The Centennial Celebration of the County Medical Society.—On Wednesday of the coming week the Medical Society of the County of New York will celebrate its one hundredth birthday by a dinner at the Hotel Astor. The price of the dinner ticket has been placed at six dollars. Members are privileged to invite guests. There will be some good speaking, though not too much, and it is hoped that the celebration will be a notable one and worthy of the important occasion.

Colony for Epileptics in Illinois.—Under the auspices of the Children's Hospital Society, an organized movement for the establishment of a State colony for epileptics was started at a public meeting at the Chicago Women's Club, Wednesday, March 14. The principal speaker was Dr. William P. Spratling, medical superintendent of Craig Colony, New York, who spoke of the good work that was being done at Sonyea, where the colony for epileptics is located. He was followed by Drs. V. H. Podstata, Daniel R. Brower, L. Harrison Mettler, and Sydney Kuh. Dr. Frank S. Churchill acted as chairman of the meeting in the absence of the president. The cooperation of the Federated Women's Clubs of the State, of medical societies, and of philanthropic and charitable societies is to be sought for an appeal to the legislature for financial support.

Eastern Illinois Ophthalmological and Otological Society.—A meeting of this society was held recently in Decatur to perfect organization, at which the following were elected as officers: *President*, Dr. James W. Sanders, Decatur; *Vice-President*, Dr. Benjamin Gleeson, Danville; *Secretary-Treasurer*, Dr. Charles P. Hoffman, Danville. In its membership the society embraces the cities of Danville, Mattoon, Decatur, Champaign, Bloomington, and Paxton. It has a membership at present of twenty-one.

Chicago Union Hospital.—This institution contemplates the erection of a four-story brick building to cost $35,000. A permit has already been issued for putting up such a building.

A Summer Course in Hygiene.—The University of California, Berkeley, announces a special course in public health and sanitary science at the next summer session of the university, June 25 to August 4, providing that enough applications for the course are made before April 1 to warrant the undertaking. Water supplies and the disposal of sewage will be discussed by Charles Gilman Hyde, C.E., assistant professor of sanitary engineering, and recently a member of the Massachusetts State Board of Health. The bacteriology of the infectious diseases will be taken up by Archibald R. Ward, assistant professor of bacteriology and director of the State Bacteriological Laboratory.

An Unsanitary Prison.—The recently appointed resident physician at San Quentin prison, California, is said to have found the conditions there extremely unfavorable for surgical work, owing to scarcity of modern instruments and appliances. In a formal report it is stated also that many of the prisoners have the appearance of advanced tuberculosis, but that no careful physical examinations have been made and that there is no attempt at segregation. It is expected that the new interne will effect the needed reforms.

Smallpox Near Merced, Cal.— Dr. N. K. Foster, secretary of the State Board of Health, has sent a warning to other cities against the danger of a spread of an epidemic of smallpox that has broken out among railroad employees of a new road being built from Merced.

A Good Fee Lost.—A physician of Redlands, Cal., sued the Sunset Telephone Company for $1,200 for services rendered to an injured lineman in his private hospital, but the case was nonsuited on the ground that authority had not been given by the company for charging the account to it.

Portland Hospital Destroyed.—The Multnomah county hospital was destroyed by fire on March 10. Four nurses, Mrs. M. C. Drain, Miss Joie Call, Miss Jennie Freeman, and Miss Marie J. Clark, have received especial mention for bravery in saving the lives of the inmates, more than forty in number.

Mosquitos in New Jersey.—The bill appropriating $350,000 for the purpose of mosquito extermination in New Jersey passed the Senate last week. The cost of draining with the processes devised by the Mosquito Department is about $1.40 an acre. Newark last year drained 3,500 acres at an expense of $5,000. The appropriation about to be made will dry up all the 200,000 acres of marsh land still remaining. The work, it is calculated, will take five years. As soon as the act is passed the department will begin work on the great meadows between Jersey City and Rahway and another 20,000-acre tract in the southern part of the State. Every Town Committee and improvement club has established its mosquito committee to join hands with the State department.

The "Colorado Medical Journal."—The formal retirement of Dr. William N. Beggs as editor of the *Colorado Medical Journal* is announced, and Dr. T. Mitchell Burns, who has for some time officiated as consulting editor, has been chosen as his successor. The position of consulting editor will be assumed by Dr. J. N. Hall.

Yellow Fever at Panama.—A case of yellow fever was reported from Panama on March 23, as having occurred at Bocas del Toro. It is probable that Panama will appoint as health officer at Bocas del Toro some member of the staff of Col. Gorgas, under whose supervision the town will be fumigated and the routine sanitary regulations will be enforced.

Quarantine Regulations Against Havana.—It has been decided at Washington that the crews of vessels plying between Southern ports of the United States and Havana need not be yellow fever immunes. This ruling will be a great advantage to the shipping companies in both countries.

Association of American Medical Colleges.—At the annual convention of this association, held in Pittsburg, the following were elected as officers: *President*, Dr. George M. Kober of Washington, D. C.; *Vice-Presidents*, Dr. C. F. Waite of Cleveland and Dr. H. W. Loeb of St. Louis. The next convention will be held at Richmond, Va.

American Gastroenterological Association.—The ninth annual meeting of this society will be held in Boston, Mass., on June 4 and 5, 1906.

The Antivaccination Movement is so strong in Toronto, Can., that the public school board, in spite of protests from the local medical societies, has decided to allow unvaccinated children to attend the institutions under its control.

Obituary Notes.—Dr. Charles Louis Fincke of Brooklyn died on March 19, at the age of thirty-three years, as the result of an infection received while operating. Dr. Fincke was graduated from Yale University in 1896 and from the Long Island College Hospital in 1900.

Dr. G. E. E. Sparhawk of Burlington, Vt., died on March 14, at the age of seventy-seven years, after a year's illness. He graduated from the Hahnemann Homeopathic College in Philadelphia in 1853. For years he was the only exponent of homeopathy in Vermont, and after having practised in several other places he removed to Burlington in 1878.

Dr. B. W. Carpenter of Burlington, Vt., died on March 20, at the age of sixty-nine years. He was graduated from the University of Vermont in the class of 1857, and served as surgeon through the Civil War. He retired from active work fifteen years ago.

Dr. William N. Riley of Malden, Mass., died on March 16, at the age of twenty-six years. His death was ascribed to heart failure brought on by

exhaustion following a walk of several miles to attend a patient in the height of a severe snowstorm. He was graduated from the Harvard Medical School in 1899 and began practice in Malden a year later.

Dr. Francis Brick of Worcester, Mass., died of apoplexy on March 14, at the age of sixty-seven years. He was graduated from the Homeopathic Hospital at Cleveland in 1861 and removed to Worcester in 1875.

Dr. Nicholas J. Dorsey of Galesburg, Ill,. died of heart disease on March 9, at the age of eighty-four years. He was graduated from Williams College in Baltimore and in the early fifties he went to Indianapolis, Ind., where he practised until the outbreak of the Civil War, throughout which he had charge of the Indiana hospital corps.

Dr. Francis J. Wennerberg of Boston died of pneumonia on March 17, at the age of thirty-seven years. He was graduated from the Harvard Medical School in 1893.

Dr. Alonzo H. Boyer died at Philadelphia on March 18, at the age of sixty years. He was graduated from the medical department of the University of Pennsylvania in the class of 1868. At the outbreak of the Civil War he enlisted as assistant surgeon in the 200th Regiment, Pennsylvania Volunteers, serving throughout the war.

Dr. William Kroh of Los Angeles, Cal., died on December 11, 1905, at the Good Samaritan Hospital in that city of nervous prostration. Dr. Kroh was a native of Baltimore and was graduated from the University of Maryland in the class of 1886.

Dr. H. Hoyle Butts of this city died suddenly on March 26, at the age of forty-three years. He was a graduate of the Medical Department of the University of New York in the class of 1885. He was a member of a number of local, State, and National medical societies, and was an attending surgeon to the Manhattan Eye and Ear and Throat Hospital.

Obituary.

ROBERT OGDEN DOREMUS, M.D., LL.D.,

NEW YORK.

Dr. Robert Ogden Doremus died on March 22, at the age of eighty-two years, after an illness of ten days. Dr. Doremus was a notable figure in the development of scientific work and instruction in this city, and did much to stimulate popular interest in physical and chemical lore. He was among the first to establish chemical laboratories for instruction, and was long a leading expert in chemistry and toxicology. His father was one of the founders of the New York University, and Dr. Doremus received the degree of A.B. from that institution in 1842, the degree of A.M. in 1845, and the degree of M.D. in 1850. He was one of the founders of the New York Medical College, the Long Island Hospital Medical College, and Bellevue Hospital Medical College, in each of which he established courses of laboratory instruction in chemistry. From 1853 to 1861 he was Professor of Natural History at the Free Academy, now the College of the City of New York, and he later served the same institution as Professor of Anatomy and Physiology and as Professor of Chemistry and Physics. From 1892 until 1902 he was vice-president of the college.

Dr. Doremus made many discoveries and inventions in his special subjects, among which were researches on light, on the daguerreotype, on disinfection, and on gunpowder. He was a constant contributor to the literature of his subjects, and was a member of the Medical Advisory Commission which established the present Board of Health. He was a graceful speaker, whose impressive personality greatly aided his work as a teacher. Dr. Doremus was an accomplished musician and served for a number of terms as president of the Philharmonic Society.

Correspondence.

OUR LONDON LETTER.

(From Our Special Correspondent.)

KING'S AND SUNDAY FUNDS—OUT-PATIENT ABUSE—SCHOOLS AND HOSPITALS—MALIGNANT DISEASE OF APPENDIX—TREATMENT OF CHRONIC RENAL DISEASE—CANCER AND BOYEN'S METHOD—LIVERPOOL TROPICAL SCHOOL—INSTITUTE OF MEDICAL SCIENCES—OBITUARY.

London, March 9, 1906.

To meet the views of the King's Hospital fund as to the separation of the school funds, the meeting of the Westminster Hospital governors has decided to raise the students' fees about 10 per cent.—an amount which will not make it the most expensive—and to ask subscribers to contribute separately or to earmark the amount they are willing to devote to the school. Sir Douglas Powell, who is on the committee of the King's fund and was present, emphasized the great value of the medical school, and said that the plan adopted at his hospital (Middlesex) of asking subscribers to earmark the amount for the school, had so far worked satisfactorily.

Out-patient abuse was discussed at a meeting of the Sunday Fund presided over by the Lord Mayor, last week. The committee's report said there is not any serious abuse of the out-patient departments, and if any should exist it can be effectually met by a system of investigation by a competent staff, who should visit the homes of patients. The Rev. C. H. Grundy thought there was great abuse and advocated a small fee being charged. Dr. Glover asserted that there was a general admission of abuse of the out-patient departments at all the large hospitals; that it could be checked was proved by the fact that in one the numbers had fallen by half on an efficient system of inquiry. Mr. Sydney Holland, of course, protested that there was no abuse! He ought to know, but wilfully shuts his eyes to the effects of his own doings. It is intended to apply for a royal charter for the fund.

The first annual meeting of the Amalgamated National and Royal Orthopedic Hospitals was held on February 28. The amalgamation was reported to be now complete, the King and Queen had become patrons, and a royal charter issued. Many children admitted to the hospital know positively nothing. A school is carried on in the wards under the auspices of the County Council, and in addition to the usual instruction some amount of training for suitable employments is afforded. Plans for building a new, highly-equipped hospital have been prepared.

The Seamen's Hospital Society's annual meeting was held on February 28, when resolutions were passed commending the work of the committee in the establishment of the London School of Tropical Medicine and within the last year the London School of Clinical Medicine. Both these branches of the society's work elicited warm approval on the part of several speakers and funds were asked for to support the two valuable schools, as well as hospitals, in which 26,000 sick and injured seamen are treated annually.

Malignant disease of the appendix vermiformis formed the subject of a paper by Drs. Rolleston and Lawrence Jones at the Medico-Chirurgical's last meeting. They reviewed the recorded cases in chronological order. These numbered sixty-two, but only forty-two were considered undoubted. Of these forty-two, thirty-seven were carcinoma and seventeen spheroidal-celled, with an average age incidence of 24.2 years. Of five cases of columnar-celled, this age was 62, corresponding with age incidence in these parts of the intestine. Of the forty-two cases, thirty-four were reported since 1900. It seems the condition cannot be diagnosed before operation. The results of excision were good, only four deaths following within two weeks. The operation need rarely exceed simple excision of the appendix, but in three cases a portion of the cecum was removed in one some glands, in two the entire cecum. The growth was usually localized and rarely diffuse. In two cases a stercolith was found.

Mr. McAdam Eccles related a case of primary cancer of the appendix in a young man of eighteen, who had had some attacks of pain in the right iliac fossa, with tender-

ness and some rise of temperature, and in the last a distinct induration. A "split-made opening" was made over the mass, exposing the cecum fixed by adhesions in the fossa, and behind it a hard mass, evidently a diseased appendix. It was separated with difficulty, and was greatly thickened, with an external circumference of 2¼ inches. One or two glands removed were unfortunately not preserved. Uninterrupted recovery followed, and the patient was quite well on February 19, twenty-one months after the operation. Two whitish patches were found in the walls of the appendix, quite distinct from one another and supposed at first to be tuberculous, but on microscopic examination were found to be spheroidal-celled carcinoma.

Mr. Jefferson Faulder mentioned a case in which the appendix on removal was found to be infiltrated with columnar-celled carcinoma undergoing spheroidal-celled transformation. This form is usually thought very malignant, but seems not so in the appendix. The patient is now in good health, four years after the operation. He suggested the growth might be regarded as endothelioma.

Dr. Pitt thought lymphoidenomatous growth might start the disease, and Dr. French thought the inflamed lymphatic tissues might resemble the case.

Dr. Rolleston protested against any unusual form being called endothelioma, which was a growth derived from endothelial cells, but not necessarily malignant. The regular arrangement of the connective tissue or uniform size of the cells were against the possibility of the growth being of an inflammatory nature.

The treatment of chronic renal disease was brought before the Medical Society on February 26 by Dr. Samuel West, especially in regard to points on which opinions were unsettled. Chronic parenchymatous nephritis was first considered, and as it represents the results of an inflammatory process, the problem is to promote the growth of healthy renal cells by a high state of nutrition. Patients were often kept too long on an exclusively milk diet. At all times meat extracts and alcohol must be avoided, but Dr. West could not see why eggs in moderation should be excluded, nor did he see why white meat should be ordered and red meat forbidden. Confinement to bed or one room might also be too prolonged, as the health suffered. Fresh air was beneficial if chills were avoided. Treatment must not depend on albuminuria only, but other urinary symptoms must be considered. Drug treatment should be of a general kind, modified so far as the kidneys required.

In granular kidney, the problems were different, varying with the stage. Early, much might be done if the condition were recognized, to retard its progress. Life might be active with moderate, regular exercise, but overexertion and exposure must be shunned. In the middle stage, when the heart was hypertrophied and the arteries thickened, we must guard against cardiac failure, rupture of vessels, and intercurrent nephritis. The last was not generally recognized as a danger, but was important. In the third stage, symptoms were variable, might suggest mischief in any organ rather than kidneys. Arterial tension varied, and the pulse afforded the best indication for treatment. Low tension must be raised by diet, stimulants, digitalis, ergot, and adrenalin. High tension should be reduced by diet, purgatives, diaphoretics, and baths; also iodide of potassium and nitroglycerin. Pilocarpine was less risky than supposed and was useful for restlessness, insomnia, and threatening uremia. Cannabis was superior to opium as a hypnotic. Some symptoms suggest that the kidney has an internal secretion, and though there is no proof of this, the administration of renal extracts has seemed useful, but a stable preparation would be necessary.

Sir Lauder Brunton advocated in the middle stage strophanthus, as it did not constrict the vessels like digitalis. For high tension, 20 grains nitrate potassium with 1 gram sodium nitrite, in a tumbler of water, every morning. This could be continued for years. Extracts of different parts of the kidney differed—probably they should be made from the cortex.

Dr. De Haviland Hall advocated milk diet for at least three or four weeks, and had seen complete recovery from it, the patient passing as a first-class life for insurance. He did not support butcher's meat too soon, poultry and fish being safer. He agreed on the value of pilocarpine. Decapsulation for large white kidney had been done in America rather frequently. In granular kidney, which seldom began before the age of forty to fifty, he spoke of the significance of skin lesions. Strophanthus he combined with potassium iodide. Headache with high tension was relieved by very small doses of trinitrine, one-third of a minim, repeated often if needful.

Dr. C. W. Chapman referred to the mental effect on a patient who was told he had Bright's disease. For the asthmatic attacks colchicum, iodide potassium, and lobelia were useful.

Dr. West in reply repeated that although milk treatment was the very best in the early stage, he believed it was often continued too long. He was sceptical about decapsulation. The age of onset was nearly impossible to decide. Probably many cases of physiological albuminuria in early life eventuated twenty or more years afterward in granular kidney.

At the annual meeting of the Cancer Hospital last week, Mr. F. Bowreman Jessett warned the public against placing any reliance on reports of cures in the sensational section of the daily press, which were calculated to cause disappointment. Even though, under treatment, a case might receive some alleviation for a time, a couple of years must elapse before it could be seen whether any permanent benefit resulted. The surgical and pathological staff had visited Paris on the invitation of Dr. Doyen, in order to carefully study his method of treatment, but Mr. Jessett regretted to say that in not one single case had any appreciable good been done by injection of the serum, while in some instances positive harm had resulted. So far, therefore, as the Doyen treatment was concerned, nothing was likely to come of it.

The Liverpool Tropical School has just issued its annual report. A sympathetic allusion is made in it to the untimely death of Dr. J. E. Dutton while engaged on the Congo in investigating trypanosomiasis and tick fever. The main points of interest in the work of the school are also outlined, and it is said that the generous support of the public has not been relaxed. At the same time further support is desired, to enable the school to continue the investigations already in hand, as well as to open new fields of research.

The proposed Institute of Medical Sciences of the University promises to be a success. The Goldsmith's Company has promised a grant of £10,000 on the assumption that a site for the building is provided in South Kensington.

Surgeon-General Thos. E. Charles, M.D., LL.D., Ed., F.R.C.P., Lond., K.H.P., late of the Indian Medical Service, died on February 22, aged seventy-one. He went to India in 1856, was through the sieges of Delhi and Lucknow, and was awarded medals and clasps. Later he became professor in the Bengal Medical College. He founded and superintended the building of the Eden Hospital. In 1880 ill health rendered a return to Europe desirable, and he resigned. Afterward he practised at Cannes and later still at Rome. He was greatly admired by all who knew him.

Deputy Surgeon-General Henry C. Herbert, M.D., F.R.C.S., died on March 2, after a short illness.

Dr. Tuckwell, many years leading physician of Oxford, died on March 2, in his seventy-second year. He was a Fellow of the London College of Physicians from 1870.

OUR BERLIN LETTER.

(From Our Special Correspondent.)

STATUS OF THE MEDICAL PROFESSION—NEISSER'S WORK IN JAVA—RADIOSCOPY OF THE STOMACH—AN INSTITUTION TO COMBAT INFANTILE MORTALITY—GASTRIC ULCER—VON BEHRING'S TUBERCULASE—KOCH'S RESEARCHES ON RELAPSING FEVER.

BERLIN, February 20, 1906.

At the end of 1905 the total number of Berlin physicians was 2,636; this means a proportion of one physician for 772 inhabitants, and is two less than in 1904. In greater Berlin—that is, Berlin with all its suburbs—the figure amounts to 3,789, which is 11 more than in 1904, and gives one physician to 788 inhabitants. According to this increase the total number of German physicians has increased 1.9 per cent. and amounts to 31,041, so that in Germany also the medical profession need not expect more hopeful conditions for the future. New dangers are constantly arising which aggravate the physician's position. There are hardly any greater enemies to be found than the representatives of the different Krankenkassen, or lodges for medical treatment, but even these are in accord against a new danger. In Germany, and especially in Berlin, the project has been started of founding a new lodge, the "Mittelstands Kasse," with the intention of cheapening medical service. The now existing lodges generally have members whose incomes do not surpass two thousand marks, but because the term "Mittelstand" does not draw exact limits the whole German population is eligible for membership in this new lodge excepting only the upper ten thousand. All medical societies are discussing the matter, and I hope soon to be able to report energetic measures against this extraordinary danger.

Two guests at our medical societies have excited great interest; the first was Neisser, the well-known dermatologist from Breslau, who spoke before the Dermatological Society on the experiences gained during an eight months' stay in Java devoted to studying the syphilis of apes. Even in this tropical region difficulties were experienced, for, though the lower monkeys are easily obtainable, the orang-

outangs and gibbons are expensive and delicate, so that three-quarters of them very promptly die. On the other hand it was also difficult to get hold of cases of recent syphilis, because the natives are accustomed to seek medical aid only in severe cases, and object to all surgical measures. Although Neisser detailed a great variety of experimental observations of much interest, the chief results of all the investigations were the following: (1) The fact that the poison could be modified by passage through a number of animals; (2) that we now have the means of producing syphilitic poison in every quantity. The second guest was Holzknecht of Vienna, who addressed the medical society on the use of the Roentgen rays in relation to gastric disorders, and especially in regard to cancer of the stomach. The examination is made possible by filling the stomach with food mixed with subnitrate of bismuth and, instead of resorting to radiography, as has formerly been advised, the speaker made direct observations by means of the fluoroscope. In the course of an extensive series of observations it was discovered that 80 per cent. of adult stomachs were not in the horizontal position as we are accustomed to see them in the cadaver and at laparotomies, but were stretched longitudinally, with a rising curvature at the pyloric end, the lowest part reaching below the navel. Although this condition was found in 80 per cent. of all cases, the speaker believed that it was an abnormal position, as children less than four years of age possess a horizontal stomach, and the other form is mechanically very unfavorable for the disposal of food. By the same method gastric tumors may be demonstrated, for if the bismuth meal does not fill the entire stomach, but on the screen shows notches along the border which cannot be obliterated by manipulating the stomach through the abdominal wall, the diagnosis of a tumor is very probable. Twelve cases which could not be recognized by palpation as having an abnormal stomach showed this sign, and in every case the operations confirmed the diagnosis of tumor.

Our emperor and empress have refused all gifts on the occasion of their silver wedding, and the money which was to be spent in that way is to be employed for various charities, such as homes for the blind and aged. At Berlin many prominent personages held a meeting on January 11, at the Reichstag, to found an institution for the purpose of combating infantile mortality, as a silver wedding gift to the emperor. Heubner has urged that the new institution be devoted to the purpose of determining the best means of securing artificial food for infants. Dietrich presented a plan for the proposed institution. During the last month of her pregnancy the prospective mother is to be admitted and prepared for nursing by good food and care of the breast. After birth the mother is to be transferred to a mothers' home, where observations can be made on the best methods of nursing; artificial feeding can be studied in another department devoted to children whose mothers have no milk. In still another department children with intestinal diseases will be cared for, and provision is also to be made for furnishing to the poor, free of charge, milk of a high quality, which is to be obtained from a special department intended for investigating the question of milk production. Charlottenburg has donated a site for the institution, and there is hope that the first buildings will soon be erected.

At the medical society Senator gave some therapeutic suggestions in regard to treating ulcer of the stomach. The diet he recommends is intended to avoid the starvation involved in the ordinary plan of treatment, while at the same time any tendency to fresh hemorrhages will be checked. The foods he employs are gelatin, fat, sugar, and albumen. The great advantage of the gelatin consists in its hemostatic properties; the sugar is given in the form of an eleosaccharate mixed with a solution of gelatin; the fat is given in frozen balls of whipped cream. On this diet the patient is well nourished, without encouraging the occurrence of fresh hemorrhages.

At the annual meeting of the German Agricultural Society much interest was aroused by von Behring's paper on the fight against bovine tuberculosis, and on the production of hygienic milk. Von Behring said that the investigations now under way in his institute were a continuation of the researches reported on last summer at Paris and were not concerned with the question of bovovaccination; the latter question he considered had been brought to a certain degree of perfection, and would have been placed in other hands were it not that he required extraordinary sums for the new researches, which were to be devoted to human tuberculosis. He repeated his warning uttered at Paris against attempts to employ bovovaccination in cases of human tuberculosis, and stated that he would never assume the responsibility of injecting living tubercle bacilli into infants for the purpose of preventing tuberculosis. Bovovaccination can be used only on young calves, and the injection of the material into older cows had not proved practical. The same amounts which did not affect the new-born calf produced disease and death from edema of the lungs in cows. If the vaccine were injected simply under the skin the intended effect was not produced, for a local tuberculous deposit was set up from which living bacilli might enter the blood-vessels and infect the milk. At Paris the speaker had mentioned a preparation which was free from bacilli, and therefore could not infect the milk, and yet gave to the cows a certain immunity. This preparation, called tuberculase, was a yellow fluid and looked like wax. Its injection was to be repeated at intervals of several weeks, but as it could be given subcutaneously by untrained persons and was not very expensive, there would be no difficulty in its general introduction. On treating with tuberculase cows that were secreting tubercle bacilli in their milk the organisms disappeared after several weeks, and this result gave him the idea of using tuberculase in the treatment of human tuberculosis. The conditions in the latter case were quite different, however, and even at Paris he had never spoken of a remedy for curing tuberculous tissues, but only of a means for immunizing young individuals against the disease. At the most this remedy enabled the human body already suffering from tuberculosis to become resistant against a new infection. In closing, von Behring said that he believed that he would soon be able to produce a milk from cows that would serve for the immunization of infants, and that even though years might be required to accomplish this end he felt sure of attaining it. In the discussion that followed Damman of Hanover argued against several points of von Behring's paper and asserted that it still was better to kill diseased cows and compensate their owners. Von Behring answered that most veterinary surgeons did not believe this, for the demand for bovovaccination was increasing every month. In speaking of the fear that the bovovaccine might infect the vaccinator von Behring said that none of his companions had become ill and that those who were tuberculous had improved after working with the remedy.

It was natural that all Berlin should be anxious to hear the report of Robert Koch's last visit to Africa, and the great hall of the Medical Society was completely filled when Koch read his paper on African relapsing fever. He followed the caravan route from Daresalam to Morogoro and from there still further into the interior. This journey was the means of clearing up what has long been a mystery, for, although the parasite of European relapsing fever has long been known, the method of its transmission from man to man has until now remained undiscovered. Koch was able to show, however, that the spirochete which causes the African relapsing fever was also contained in the bodies of certain ticks, which feed only on human blood. When full grown, the insect attains the size of a lentil, and it was found that the specific organisms of the disease could be found in the tissues of the tick, and particularly about the ovaries. Ticks of this species were found to be very common in the shelter huts along the caravan route, but Koch and his white companions escaped infection by sleeping in a tent pitched a short distance away from the road, while of the native attendants who slept in the huts several developed relapsing fever. The disease is very refractory to treatment, as even quinine is ineffectual, and at present the only remedy appears to be to warn travelers to avoid the shelter huts along the caravan route, the dirt floors of which seem to be full of the ticks.

OUR LETTER FROM THE PHILIPPINES.

(From Our Special Correspondent.)

BERIBERI—CHOLERA—THIRD ANNUAL MEETING OF THE PHILIPPINE ISLANDS MEDICAL ASSOCIATION.

MANILA, P. I., February 14, 1906.

THE regular monthly meeting of the Manila Medical Society was held in the library of the laboratory building of the Bureau of Science, on Calle Herran, at 8.30 P.M., Monday evening, February 5, 1906. Dr. Maximilian Herzog, the pathologist of the Bureau of Science, read a paper on beriberi, which he illustrated with special lantern slides. It will be remembered that Dr. Herzog has recently spent several months in Japan, in making a special study of the disease, particularly with regard to its etiology and pathology. He prefaced his remarks by stating that he was very sorry that he had nothing new to offer. In the main, his paper was very much in accord with the views expressed by Hamilton Wright in his recent article on beriberi. Dr. Herzog was of the opinion, however, that there were not yet sufficient data to support the view of Wright that the toxins of the disease entered the system through lesions of the stomach or duodenum, and stated that the most careful examination of the walls of the stomach or intestines in a

great number of autopsies which he had performed in Japan failed to show anything unusual or different from that found in subjects who had died of other diseases. With regard to the etiology, he stated that all the theories which had been advanced up to the present time were very unsatisfactory.

Referring to the Russo-Japanese war, he stated that over fifty thousand Japanese soldiers were afflicted with the disease during the war; that the sanitary and hygienic measures which were taken had no appreciable effect in preventing the outbreaks. The same prophylactic measures which were so successful in avoiding dysentery, typhoid fever, and other diseases incident to military campaigns, were entirely ineffectual when applied to beriberi. He stated that one of the principal Japanese surgeons attributed the outbreak of beriberi among the troops to the bad quality of food, particularly rice, which had been purchased in Hongkong. This experience accords with the results of Takaki's dietary reforms in the Japanese navy which led to a practical extinction of the disease in that service. The lantern slides which he exhibited showed the degeneration of the axis cylinder, and particularly the roundish deposits under the myelin sheaths.

At the present time the Bureau of Health is carrying on a vigorous campaign to eradicate cholera from the provinces of Pampanga, Bulacan, and Nueva Ecija. The infected territory has been divided into small districts, and a medical inspector of the Bureau of Health has been placed in charge of each one of them. The measures were made as simple as possible, and consist mainly of earth closets being installed in all the villages, the actual cases of cholera being isolated and the premises thoroughly disinfected, and the people induced to boil their drinking water. Apparently this campaign is meeting with considerable success. At any rate, the number of cases is being gradually reduced. At the beginning of the week there were about eighty cases per day, until now the number of cases has fallen to about twenty, and it is hoped that before many days, if this rate of improvement continues, the epidemic will be at an end.

The total number of cases of cholera in the city of Manila since the outbreak has been 272, and 241 deaths; the total number of cases in the provinces has been 3,083, with 2,281 deaths.

The third annual meeting of the Philippine Islands Medical Association will be held in the library of the Bureau of Science, commencing February 28, 1906, and extending for three successive days thereafter. An excellent program has been arranged. A paper on "Radium and Radioactivity" will be read by Prof. P. C. Freer, formerly of Ann Arbor. A paper entitled "Uber die Typen der Dysenteriebacillen und die Serum-Therapie der Dysenterie" will be read by Prof. K. Shiga of Japan, and another paper, entitled "Ueber die Bekämpfung der Pest in Japan," will be read by Prof. S. Kitasato. Another paper, entitled "Immunization Against Plague: Comparison of the Value of Protective Inoculation with 'Aggressin,' with that of Vaccination," will be read by Dr. Richard P. Strong. The above papers are all by men of international reputation, so that this meeting of the Philippine Islands Medical Association will be of particular interest not only to the Philippine Islands, but to the entire scientific world as well.

THE RELAXING WARM BATH IN GYNECOLOGICAL EXAMINATIONS.

To the Editor of the Medical Record:

Sir:—Referring to your article in the issue of March 17, 1906, giving credit to Profanter for a novel procedure consisting in placing the patient in a relaxing warm bath for gynecological examination, I beg to say that the general principle is by no means new. In *International Clinics* for April, 1899, I discussed the general subject of "Palpation in the Warm Bath." At this time I had practised the method for a considerable time and stated that I had gotten the hint from some German source which I could not definitely state. Since that time Sticker has written on the method and, I believe, has claimed originality for it. Whether the article from which I derived the idea and brought it to the attention of the American profession was his or not, I am unable to state. While I have frequently used the method in external palpation of the pelvic organs, I do not recollect ever having used it for the combined vaginal and abdominal palpation. But as the method was published in Germany at least as early as 1898, it seems incredible that it should not have been used in bimanual examinations in the ordinary sense long before the appearance of the article which you quote.

A. L. Benedict, M.D.

Buffalo, N. Y.

Progress of Medical Science.

Boston Medical and Surgical Journal, March 22, 1906.

Cerebral Seizures with Suboccipital Pain; Miliary Cerebral and Gross Vertebral Aneurysms.—An elaborate history is given by W. D. Ruston and E. E. Southard of a woman of sixty-nine years with moderate arteriosclerosis and an enlarged heart. She felt attacks of severe boring pain localized in an area the size of a half dollar in the suboccipital region, had occasional slight chills with an elevation of temperature, showing morning remissions. Leucocytes over 17,000. Death came in coma, two hours after a sudden cold feeling in the forehead on the nineteenth day. An anatomical summary of the autopsy findings so far as concerns the nervous and vascular systems is as follows: general arteriosclerosis (aortic, coronary, cerebral, splenic, renal). Fusiform aneurysms of both vertebral arteries. Miliary aneurysms of cortical and ganglionic arterial systems. Extensive multiple cerebral hemorrhages (of varying age) in substance of anterior poles of brain and elsewhere, with oozing into superficial pia mater. Summaries are given of the histories of various similar cases already on record, though none are exactly like that here described. Their own case the authors classify as of the "imitative" type. The patient's peculiar localized pain was probably caused through pressure of the vertebral aneurysms aided by heightened intracranial pressure attending the cerebral hemorrhages. They note also that the search for the particular cause of a given pain is not always as minute as it might be. Pains are, perhaps, too readily classed as functional. The orthopedists occasionally insist on the possible relation of neuralgia to the pressure of dilated or varicose veins upon the regionary nerves. The present case brings out the possibility that arterial disease may effect the same result in one of the favorite sites for functional pain.

New York Medical Journal, March 17, 1906.

Teaching the Deaf Child to Hear.—G. H. Makuen presents the following conclusions: First, the hearing of the deaf child may be greatly improved by the systematic use of oral gymnastics. Second, the speaking voice used in close approximation to the ear is the most effective form of oral gymnastics for children. Third, the training of speech should be carried on simultaneously with the hearing exercises. Fourth, The degree of success obtained will depend largely upon the patience and skill of the teacher.

Surgical Intervention in Benign Gastric Lesions.—A. J. McCosh considers that as a result of modern surgery of the stomach we are logically enabled to draw the following conclusions: (1) That many gastric symptoms formerly considered as purely functional are caused by distinct anatomical conditions or pathological lesions. (2) That for diagnostic purposes the stagnation test is of much greater value than is any chemical examination of stomach contents. (3) That spasmodic pyloric contraction frequently occurs as the result of derangement of gastric secretion or abrasions of the mucous membrane of the stomach or of the duodenum. (4) That gastric hemorrhage frequently occurs without the existence of the typical round ulcer, the bleeding emanating from minute abraded spots or cracks, which may be scattered about throughout a patch of intensely congested mucous membrane. (5) That not uncommonly, large inflammatory masses, constituting a palpable tumor, may exist, caused by and surrounding an ulcer. (6) That duodenal ulcers are of frequent occurrence. (7) That in the great majority of cases of contracted pylorus, whether it be due to pyloric spasm, inflammatory hyperplasia of the circular muscular fibers, or stricture with adhesions from an ulcer, a gastroenterostomy will effect a cure, or at least markedly relieve the symptoms. (8) That in a long series of cases, the mortality of this operation should not be over 5 per cent., provided that, through neglect, the patients have not been allowed by so-called conservative treatment to drift into a semimoribund condition. (9) That, in cases of simple dilatation with atrophy of the stomach without constriction of the pylorus, a gastroenterostomy will generally fail to cure the patient. (10) That, following gastric operations there must be, if we strive for perfect results, continuous dietetic and hygienic treatment, extending over months or even years.

Etiology of Acute Articular Rheumatism.—R. I. Cole declares that three possible theories of the etiology of rheumatism are worthy of careful consideration. First, that it is a definite, specific, infectious disease, the cause of which we do not know, and that the cocci which have been isolated are secondary invaders. Second, that there is no such specific disease as acute articular rheu-

matism, but that the cases grouped under this term are those mild and moderately severe cases of general streptococcus infection in which the joints and heart are generally involved. Third, that acute articular rheumatism is due to a special form of streptococcus, which at present we have no accurate method of distinguishing from *Streptococcus pyogenes*, but which, owing to the specific character of the lesions induced in man, must possess special characteristics. This author does not think we are justified in using the term "*Micrococcus rheumaticus*," any more than we are in saying *Micrococcus cyanogenus*, or of ordinary *Diplococcus pneumoniæ* differing from the *Micrococcus lanceolatus*, which causes a great variety of infections. Further study may show that the streptococci isolated in rheumatic fever have special features. This point is not yet proven, and this proof, when presented, must amount to more than a mere demonstration of differences in degree of experimental lesions produced in animals. At least, such differences must be shown to be constant.

Causes and Cure of Cancer, and Some of the Causes of Failure in Treating Malignant Growths by X-rays and Electric Currents.—According to R. Reyburn, the following facts express the history of the causation of cancer: 1. It is a disease of senility or decay of the tissues, or at least occurs at the time when the retrograde metamorphosis of the tissues is taking place. 2. It is comparatively rare in hot climates, and especially where the diet of the inhabitants is composed chiefly of rice, or other starchy foods. 3. It is very prevalent at the present time where animal food is largely consumed; the number of cases of cancer has been found to increase in proportion to the increase in the consumption of nitrogenous or animal foods. 4. The theory that cancer is caused by a protozoon or animal microorganism, seems to be disproved by later investigations, and the probability is that cancer is simply erring epithelium which has taken an abnormal growth and development. The most potent cause of failure in treatment is the neglect of the patient to apply to the physician until the case has become hopeless. One reason for failure with the *x*-ray and electric currents, is that the application of these agents is made over too small a bodily area. It must be remembered that the cancer cells are infiltrated into the tissues over a much larger area than the apparent surface of the tumor; a space three times the size of the tumor should always be treated by either the *x*-rays or the continued current. Curative effects of these agents are manifested in one of three ways: 1. In the very earliest periods of the morbid growth these agents cure by their stimulating and nutritive effect upon the vital processes. 2. In the second or more developed condition of the morbid growth, when we apply stronger currents of electricity or give more vigorous *x*-ray treatment, we inhibit the growth of the tumor. 3. When the growth of the tumor has more fully developed, we have to depend upon the necrotic or caustic effect upon the morbid growth of strong application of the *x*-rays or powerful galvanic currents. Finally, it is to be noted that the local inflammation induced by these agents causes a zone of lymph to surround the tumor, thus incasing it and preventing its spread.

American Medicine, March 24, 1906.

Malarial Fever.—Albert Woldert gives a detailed account of his personal observations made in Philadelphia and Texas regarding the Anopheles mosquito. He says that in Philadelphia he only once failed to find the malaria carrying mosquito (invariably the *Anopheles quadrimaculata*) in the houses in which autochthonous cases of malarial fever prevailed. In Texas he has never failed to find them. He also found that the male mosquitos became more numerous as frost came on, while the females gradually disappeared. He gives a thorough description of the development of the malarial parasite in the mosquito and a full discussion of the period of incubation in the different forms of malarial fever.

Etiology of the Hemorrhagic Diathesis.—Wm. W. Carter classifies the subject as follows: (1) Infectious diseases and toxic conditions as etiologic factors. (2) Cachetic conditions. (3) Purpura hemorrhagica. (4) Hemophilia. Malaria is one of the most important causes of the hemorrhagic diathesis. The hemorrhagic diathesis is also sometimes developed in such cachetic conditions as pernicious anemia, leukemia, scurvy, chronic nephritis, syphilis, and diseases of the liver attended by accumulation of bile in the blood. Mechanical defects in the circulation, as in valvular disease of the heart and senile purpura due to atheroma of the vessels and retarded circulation, produce a tendency to bleed. Among toxic agents causing this condition may be mentioned: Phosphorus, antipyrin, mercury, and chloroform. Purpura hemorrhagica forms the connecting link between the symptomatic hemorrhagic diathesis and the pure type of the hemorrhagic diathesis or hemophilia. It cannot be classed under the head of hemophilia, as it is transient and not hereditary. Its cause is unknown. The true etiology of the affection is still unknown.

Nose and Throat Diseases From a Constitutional Standpoint.—J. L. Harkness, in discussing nose and throat diseases from a constitutional standpoint points out the intimate relation which exists between these organs and other organs of the body, as for instance, laryngitis and pharyngitis of a rheumatic or lithemic origin. He also notes the relation between varicose veins of the leg and hypertrophied tonsils, and the effect of adenoids which cause gastric disturbances and vice versa, inanition in children, etc. He calls attention to the inflammatory conditions of the sinus (with consequent systemic effects) caused by a deflected septum, and shows the close relation existing between nasal conditions and the genitalia both in normal physiological conditions and in disease.

Journal of the American Medical Association, March 24, 1906.

The Formation of Uric Acid.—L. B. Mendel discusses the formation of uric acid in the body, reviewing the later physiological investigations on the subject. The probable endogenous and exogenous antecedents are considered and the probable chemical reactions involved in the formation of uric acid from other purin bodies are given. He calls attention to the peculiar rôle of enzymes in both the formation and destruction of uric acid. The organs and tissues concerned in these processes and the factors modifying these metabolic changes are all considered and treated of in detail with full references to the leading literature on the subject. There are many admittedly missing links, especially as regards the origin and significance of endogenous uric acid. The questions yet remain to be solved as to the cause of the modifications in physiologic conditions, the variations of the endogenous output, the tolerance of the organism, the chemical regulations of the balance between formation and destruction, the differences in different species as regards purin metabolism, and still many other unmentioned questions yet remain for investigation.

Eyestrain and Digestive Organs.—G. M. Gould comments on a statement made by Dr. J. H. Musser in *The Journal*, No. 4, 1905, that the cure of so-called bilious attacks, etc., by the correction of errors of refraction is a common and familiar occurrence. He points out that it is sixteen or seventeen years since he himself first began to affirm and to reaffirm this truth, and this is the second convert made among the diagnosticians, leading practitioners, or gastrologists. Notwithstanding the admission that the fact "is familiar to all," Gould reviews the text-books and literature and shows how little mention it has received and how generally it has been ignored by the authorities. He claims that he began and for ten or a dozen years was alone in advocating the ocular origin of these diseases, and objects that after being ignored so long it should now be accepted without due credit to its earliest advocate, as simply a truth "familiar to all." While the admission, he says, is a breach in what have seemed the impenetrable walls raised by the authorities and text-book making classes, he doubts its sincerity and calls for honest reports of cases from those who must observe them, and a general scientific utilization of the truth in practice.

Faciohypoglossal Anastomosis.—A. L. Taylor and L. P. Clark report six cases, three of which were previously published in the MEDICAL RECORD about two years ago, of the faciohypoglossal operation for Bell's palsy. One of these operations was a failure on account of the degeneration of the facial nerve, in the others varying degrees of success were obtained. There was no mortality, and in three of the cases voluntary motion has returned to a very satisfactory degree. The authors discuss the operation and favor the method of lateral rather than end-to-end anastomosis as causing less functional disturbance in the long run than would be the case were the hypoglossal nerve completely divided. The time which should elapse before operation is variously estimated by authorities, the only reason for conservatism being the great possibility of spontaneous recovery. For present purposes, the authors think that the interval of a year may be allowed, since in that time returning motion would be appreciable in cases in which spontaneous recovery would occur. Where the nerve is divided and perhaps a segment removed the anastomosis should be done at once. On the other hand, there is no limit of time when the operation is contraindicated. Attention to the condition of the paralyzed muscles is imperative.

Entamœba Coli.—E. B. Vedder has investigated the stools of a number of normal individuals with special reference to the presence of *Entamœba coli*. Many of these individuals were native Filipinos, members of the Philippine constabulary; the remainder were American soldiers. The organism was found in 50 per cent. of the Americans examined, the next most common parasite, the *Cercomonas intestinalis*, being present in 24 per cent. In the natives the *Entamœba coli* was found in 70 per cent. The next most common parasite, the *Ankylostomum duodenale*, was present in 64 per cent. These findings in healthy individuals support the stand already taken by Schaudinn, Craig, and others that the *Entamœba coli* does not produce dysentery. The pathological significance of the ankylostomum is lessened by the small numbers found. It is productive of disease only when present in large numbers, and Vedder protests against the practice of making a diagnosis of uncinariasis in every case in which the ova are found, and quotes Manson, who says that serious consequences are by no means invariable in the presence of this parasite. The presence of the entamœba was determined in several cases by repeated examinations during several months without any pathological findings. Intestinal parasites were generally more frequent in the natives than in the American soldiers, which is accounted for by their habits of drinking unboiled water, while the American soldiers in the Philippines, save under exceptional circumstances, drink only boiled water.

Endoaneurysmorrhaphy (Matas).—H. Lilienthal reports a case of right subclavian aneurysm in which he attempted to perform Matas's operation, but failed on account of the not cutting off of a sufficient number of tributary vessels. The older method of proximal ligation was then followed with the result of a complete cure. In spite of the failure in this case, he thinks the Matas operation has decided advantages and would have been successful had a slightly different technique been employed. In a future similar case of sacculated aneurysm of the right subclavian, the following technique is suggested: The incision should be along the anterior border of the sternocleidomastoid muscle from a point about at the level of the cricoid cartilage to the intraclavicular notch, thence along the clavicle to its outer fourth. The sternocleidomastoid may then be divided at its insertion and the common carotid artery exposed and followed to its origin in order to find the subclavian. One should remember that anomalies are sometimes found here. Temporary ligatures should now be placed on the carotid and subclavian and the aneurysm be carefully observed, both as to pulsation and the refilling of the sac after it has been emptied by manipulation. If pulsation persists, or if there is a rapid refilling, a temporary ligation of the axillary artery is necessary. There should be no free dissection of the sac and no exposure of the smaller subclavian branches, such as the vertebral, thyroid axis, internal mammary or superior intercostal. The aneurysm may now be opened by an incision small enough to be plugged by the exploring finger and the interior of the sac carefully examined to ascertain the number of large openings. The character of the hemorrhage must be noted. It will probably not be severe and may be found to proceed from a single orifice of moderate size. There will probably not be pulsation. Endoaneurysmorrhaphy may now be performed as described by Matas, and on its completion the ligatures may be removed, first that of the carotid, second the axillary, and third the subclavian. If everything is in order the wound may be closed without drainage. In dealing with the left subclavian the steps must be changed somewhat to suit the anatomy."

The Lancet, March 10, 1906.

Vaginal Cysts.—The case of a multipara of thirty-eight years is reported by W. P. Gowland. Bearing-down sensations led to examination, which revealed two vaginal cysts. One of them was as large as a hen's egg, and situated about half way up on the left posterolateral aspect of the vagina, while the second one was of about the size of a grape and situated opposite the first one on the right side. The patient stated that five years ago she had a very difficult labor, the child being large, and she assigned the commencement of her symptoms to this date. The cysts were dissected out with difficulty and incompletely. The contents were gelatinous. The report on them was as follows: Both cysts are of the same structure. On one surface—portion of stratified squamous epithelium of vagina. On other surface—single layer of columnar epithelium of varying height (probably due to pressure within cyst) and in places distinctly ciliated. Between the two fibromuscular tissue, which, in the case of the larger cyst, is considerable in amount. The cysts are probably of Gärtnerian origin.

Bilharziosis of the Vermiform Appendix.—G. L. Crimp discusses a previously reported case of this nature. He strongly criticises the theory of infection through drinking water, for he considers it proven that the mouth is not the channel of infection. He admits that infection may occur through skin, urethra, anus, vulva, etc., but denies that it is immediate. The only question is to locate the site of intermediate generation. Evidence goes to show that this site is the liver. From this point the young adults, male and female, pass into the portal veins, mature, copulate, and work their way into various regions (among which the rectum and urogenital organs predominate), there to lay their eggs, which are the cause of the local lesions of bilharziosis

The Animal Reactions of the Spirochete of the African Tick Fever.—A series of experiments is described by A. Breinl and A. Kinghorn. They have been able to infect with the spirochete of African tick fever in addition to monkeys, a horse, a dog, rabbits, guinea-pigs, rats, and mice. The rabbits, rats, mice, and some of the guinea-pigs have succumbed to the infection. Previous observers have not been able so far as is known, up to the present, to infect any animal other than monkeys with the *Spirochæta obermeieri*. These experiments lead to the conclusion that the spirochete of the African tick fever differs from the *Spirochæta obermeieri*. While the animal reactions are different from those of the *Spirochæta obermeieri*, the pathological anatomical lesions are the same as those described in human beings who have succumbed to infection by *Spirochæta obermeieri*.

British Medical Journal, March 10, 1906.

Catarrhal Deafness.—F. F. White reports two cases in which otectomy led to a considerable improvement of deafness from catarrhal changes. It is too soon after the operation to form an idea of the permanency of the results. The author has operated eight times in all for catarrhal deafness. All his patients were definitely benefited after failure to improve under other methods of treatment.

Chloroform in Consumption.—H. D. Woodcock generally prescribes the spirit of chloroform as an inhalant, the preparation being of 5 per cent. strength. He has tried it in over two hundred cases. It has never done any harm, and the inhalation has seemed to relieve the cough, but he cannot say that the general condition of his patients has been definitely and permanently benefited.

Ophthalmology, Past and Present.—S. Snell compares the ophthalmology of his student days with that of the present time. He considers the appreciation of astigmatism and its correction by cylindrical glasses as one of the most notable advances in this specialty. The matter of correcting low degrees of astigmatism has been taken up and its importance recognized. So there has been a very large increase of prescriptions for cylinders. As a result of these advances, much relief has been afforded to patients suffering from headache and other neuroses. Visual acuteness has been increased. The important relation errors of refraction bear to headache has become increasingly understood. Possibly the most frequent cause of headache is a faulty condition of refraction, and, in less numbers, of the muscle balance of the eye. It is not yet, however, as generally recognized as it should be that the most distressing forms of headache and other neuroses are not infrequently present where no defect of vision is complained of; but it is, nevertheless, true that a careful examination discloses a faulty state of refraction, the detection of which, and its proper correction by spectacles, is usually followed by relief to the distressing symptoms. The discovery of modern antiseptics has been of inestimable advantage to ophthalmic as to other special surgery. The immediate treatment of eye injuries and the use of antiseptics has lessened the frequency of sympathetic ophthalmitis and has led to a greater frequency in the restoration of sight than was formerly the case. As to the teaching of the present day, the author thinks that the average student needs a sufficient acquaintance with ophthalmic work to meet the requirements of general practice. A knowledge of the commoner diseases and their treatment, the employment of test types and trial glasses, and, of course, the use of the ophthalmoscope, are all necessary. He does not place much value on formal lectures delivered away from the clinic, and gives in outline the plan he is accustomed to follow in teaching at his own hospital in Sheffield.

Enucleation of Fibromyoma of the Uterus During Pregnancy.—J. Stewart gives the clinical history of a primipara of thirty-five years at about the end of the fifth month of pregnancy. She presented a movable lump in the side and had been attacked with severe pain, vomiting, and rise of temperature. At first it was con-

sidered that she was threatened with a miscarriage. Later it was thought that she had an ovarian cyst—probably a dermoid—which had undergone axial rotation. Operation was deemed advisable, and it revealed a sessile mass attached to the left of the fundus. There were no adhesions and no discoloration of the peritoneum covering the tumor, showing that there was no inflammatory condition present in it. On section of the tumor after hardening there was neither hemorrhage into its substance nor beneath its capsule. The pain was due, the author believes, to the malignant influence all fibroids have upon the pregnant state—a tendency to produce abortion or miscarriage. The uterus was gently rotated so that the tumor appeared in the abdominal incision. The growth was sessile, with a broad base, and although truly subperitoneal it was deeply imbedded in the wall of the uterus, more than one-third of the tumor lying in a saucer-shaped cavity. A circular incision was made through the peritoneal covering near the base of the tumor, which latter readily shelled out of its bed. The bleeding from the tissue in which it was embedded was profuse, as none of the bleeding points would hold a ligature, the uterine tissue being so soft and friable, and the blood vessels so fragile. Pressure was applied for a time, and then the sides of the cavity were drawn together with Pagenstecher's thread. It is interesting that this patient had no uterine contractions, nor pain of any moment, although there was a considerable injury to the wall of the uterus, neither were the fetal movements interfered with. No antiseptics were used. The patient was delivered of a boy at full term.

Berliner klinische Wochenschrift, February 26 and March 5, 1906.

The Destruction of Both Eyes by the Larvæ of Flies.—Schultz-Zehden describes this remarkable case. The patient was a female vagrant, forty-seven years old, who was picked up by the police while lying unconscious in the fields. The hospital physician under whose care she first came stated that he had removed from different parts of her body a liter measure full of larvæ of the blue bottle fly. These were present in the conjunctival sacs, the nose and the ear, and at the back of the neck there was a large ulcerated area extending almost down to the bone. When the author saw the patient, both eyes had been damaged to so great an extent that their removal was necessary. In the vitreous of the one eye a large parasite was discovered, and both corneæ had been almost completely destroyed. The author supposes that a catarrhal condition had existed in this patient's eyes, the secretion of which attracted the flies and led to the deposition of their eggs in this situation, as it is well known that bluebottle flies have a predilection for placing their ova in suppurating wounds. The alcoholic coma in which the patient probably remained for some time, afforded the necessary opportunity for the development of the larvæ. In the literature of the last one hundred years the author was able to discover only one similar case, which was recorded by Cloquet in 1823. His patient was a rag-picker, who also was found lying in the fields, with both eyes destroyed in this way.

Active Lymphocytosis.—Wolff-Eisner reviews at much length the evidence in favor of the opinion that the lymphocytes possess the power of ameboid motion and active migration when subjected to suitable chemotactic stimuli, such as those afforded by the toxins of tetanus or tuberculosis. He discusses the arguments of the opponents of this view, particularly those of Israel, who maintains that the presence of lymphocytes in pleural or peritoneal exudates is to be explained by assuming that they are washed out of the lymphatics and the tissues by the accumulating fluid. The author cites his own observations on artificially produced exudates in mice, and those of Schridde on specially prepared sections, as well as the conclusions of several other investigators in support of the view that Ehrlich's dictum that the power of active migration is not possessed by the lymphocytes is no longer tenable, and that the occurrence of active lymphocytosis must now be regarded as a recognized fact.

Rachitis as an Epidemic Disease.—Hansemann considers rachitis not as a bone disease, as it is usually classified, but as a disease of metabolism, as is gout, for example. Just as renal affections are associated with gout, pulmonary inflammations and intestinal catarrhs occur in connection with rachitis. He especially emphasizes the remarkable predisposition to the infectious diseases exhibited by rachitic children, and states that his records rarely show cases of death from diphtheria, scarlet fever, or measles, in which the patients were not rachitic. This tendency is especially marked in regard to whooping-cough. In attempting to discover the etiology of rachitis, Hansemann says it is necessary to study the conditions existing in animals kept in captivity. While rachitis is the greatest enemy with which those in charge of zoological gardens have to deal, efforts to identify the cause of rachitis with particular peculiarities of diet have been entirely unsuccessful. The disease does not occur in animals in the wild state, nor in savage races of man, yet practically all wild animals are very prone to it when born in captivity or when captured while still young. It is the author's view that rachitis is simply a disease of domestication and that man suffers from it because he has become domesticated, using this term in the sense of a condition different from the natural state. The chief factors involved are the absence of a sufficiency of fresh air and freedom of motion for the young, and the validity of this argument is attested by the fact that rachitis is practically unknown in Japan, where babies are exposed to the fresh air to a much greater degree than is the case in other countries, and where their clothing is such as to permit of the greatest possible freedom of movement. The effort to restrict the spread of the disease must be based on these lines and on a general improvement in the hygienic condition of civilized man as a whole.

Disease of the Aorta in Congenital Syphilis.—Bruhns made serial sections of the entire length of the aortas of nine congenitally syphilitic children. Eight of these were still-born or died shortly after birth, and one had lived to the age of three months. The vessels showed no gross lesions, but pronounced changes were discovered in the microscopical preparations in six of the cases. The author concludes that in congenital syphilis areas of inflammation occur, situated in the outer layers of the media and in the adventitia, especially in the neighborhood of the vasa vasorum. These inflammatory foci correspond closely to those described by Chiari in acquired syphilis as productive mesaortitis. The discovery of these changes in congenital syphilis, therefore, indicates that productive mesaortitis is to be regarded as a manifestation of syphilitic disease in the aorta.

Deutsche medizinische Wochenschrift, March 1 and 8, 1906.

Flagella on Spirochetes.—Zettnow gives the following method for demonstrating flagella on fowl spirochetes, and on the spirochetes of recurrent fever. The chief difficulty in staining the flagella, he says, lies in obtaining the organisms in preparations that are free from albuminous substances, and in which the spirochetes have not been damaged by manipulation. The blood is first to be defibrinated and then centrifuged, so that the serum is perfectly clear above the white layer of spirochetes. The serum is poured off and the organisms are washed three times with physiological salt solution, being centrifuged each time in order to free them from all traces of serum. A small loop of the bacterial sediment is mixed with two drops of water and is spread immediately on cover glasses that have been freed from all grease by heat; the films must be made very thin, so that they will dry rapidly, as otherwise the flagella are likely to be destroyed. The staining is then done with an antimony mordant and ethylamine silver.

Mercury Vapor Lamps for the Treatment of the Skin and Mucous Membranes.—Kromayer describes several different types of mercury vapor lamps which he has devised, the chief feature being the introduction of a water-cooling arrangement by means of which the heat produced is absorbed so that the appliance may be brought into direct contact with the affected areas. One form of the lamp is intended for introduction into the urethra. Clinical tests have shown that as a therapeutic agent the new lamp has the same qualities as the Finsen light or the iron light, but that the results are obtained at a much greater economy of time, current, and attendance on the part of nurses and physicians. The conditions for which it is recommended are lupus, superficial cancroid, nævus vasculosus, alopecia areata, acne rosacea, eczema, acute and chronic gonorrhea, and obstinate syphilitic ulcerations.

Observations on the Action of the Streptococcus Aggressin.—Weil obtained immunity in guinea-pigs by means of injections of aggressin obtained from the pleural cavity of rabbits that had been inoculated in this cavity with streptococci. Guinea-pigs that had received several subcutaneous injections of the pleural exudate of such rabbits proved to be highly refractory to subsequent inoculations with streptococci. The process of protection was apparently effected through an inhibition of the growth of the invading organisms, which then became the prey of the leucocytes. The author suggests that if the occurrence of an effective infection is to be ascribed to the bacteria themselves, which are enabled, through their attacking substances, to render ineffective the protecting powers of the organism—not its bactericidal properties—the body that has been immunized with aggressins will be able to neutralize the attacking substances of

bacteria, and in this way to restrict their multiplication This immunity is not directed against the bacterial body, and is not bacteriolytic. As regards the aggressin theory, it is a matter of indifference whether the aggressins are formed in the animal body or outside of it, whether they are secreted by the bacteria or are constituents of the bacterial body.

The Methods of Distribution of Pulmonary Tuberculosis from the Clinical Standpoint.—Fraenkel states that it has been recognized that the tubercle bacillus may infect the body and reach the lungs in three different ways. In the first place, by being carried into the deeper air passages with the breath; secondly, by traveling to the lung through the lymphatics; and, thirdly, by entering the circulating blood in some way. Each one of these possibilities has been established by numerous observations, though some investigators have fallen into the error of ascribing exclusive significance to one or the other of them. Primary hematogenous infection occurs only *in utero*, and is then caused by tuberculosis of the placenta. Its frequency has perhaps been underestimated, as Schmorl discovered tubercle bacilli in 45 per cent. of twenty placentas of tuberculous women examined. Recently numerous observers have emphasized the importance of the lymphatics as channels of infection; for example, Weleminsky's experiments on guinea pigs showed that the entire lymphatic system of the body is intimately associated with the bronchial glands, which represent a sort of collecting ground for the lymph flow of the upper as well as of the lower half of the body. The experiments showed that no matter whether the animals were infected in the upper portion of the body or the lower, the bacilli took the most direct route to the bronchial glands. The author believes that for a part of the cases of pulmonary tuberculosis in childhood the entrance of the tubercle bacilli into the lymphatic system forms the most probable mode of infection. In adults, however, inhalation is a more important consideration. The development of acute symptoms nearly always connotes the previous existence for a considerable length of time of a much older primary focus. By far the larger number of the cases of acute pulmonary tuberculosis, excepting cases of acute miliary tuberculosis, are due to aspiration. The lesions may occur as disseminated forms, as acute peribronchitic tuberculosis, or may be due to the rapid coalescence of areas scattered through both lungs. Diabetes, influenza, pregnancy, and chronic alcoholism predispose to the development of this type.

A Case of Malignant Mediastinal Tumor.—Voltolini describes this case, which illustrates the excessive malignancy of round-celled sarcomata. The patient was a man of forty-five years, whose illness began with griplike symptoms and who rapidly developed a mediastinal growth which caused his death within eight weeks. At the autopsy it was found that the entire aperture of the thorax was occupied by a hard, grayish-white mass the size of several fists which almost surrounded the pericardium on all sides and was closely adherent to it, to the lungs, and the anterior chest wall. The ascending aorta and the arch were completely imbedded in the mass, and the arch was so constricted that it would barely admit a finger. Only the apices of the lungs were aerated.

Münchener medizinische Wochenschrift, March 6, 1906.

Water as an Enemy to Radiography.—Lichtenstein calls attention to the well-known fact that so far but little progress has been made in the application of radiography to the diagnosis of obstetrical conditions. In spite of the improvements in technique satisfactory radiographs of the fetus *in utero* have not yet been obtained. Lichtenstein considers that the explanations usually offered for this difficulty in obtaining pictures under these conditions are not altogether adequate, and states that he believes that the true obstacle to perfect work in this direction lies in the presence of the liquor amnii. He describes experiments in which he made radiographs of iron rods through layers of water of different thicknesses, his results showing that the presence of layers of fluid of any considerable depth is sufficient to make it impossible to secure good radiographs. A layer of water fifteen cm. thick is, he says, entirely impermeable to the Roentgen rays. He suggests that the poor character of the radiographs usually obtained of vesical, renal, or biliary calculi depends on the same fact, namely that the presence of the fluid ordinarily surrounding these structures hinders the penetration of the rays. He therefore suggests the advisability of more extended study of the physical laws involved in order if possible to discover some remedy.

New Reactions for Diacetic Acid.—Riegler says that the following test which he devised in 1902 has been found very satisfactory: Three c.c. of a 10 per cent. solution of iodic acid and three c.c. of chloroform are shaken up with ten c.c. of the suspected urine. If diacetic acid is present the chloroform will remain colorless, but if there is no diacetic acid in the urine the chloroform will be colored red. Lindemann has suggested the following modification, which meets with Riegler's approval: Ten c.c. of urine are acidified with five drops of 30 per cent. acetic acid, five drops of Lugol's solution are added and the mixture is shaken up with two or three c.c. of chloroform. As in Riegler's test, the presence of diacetic acid is shown if the chloroform remains colorless. Riegler points out that some urines are so dilute that the reduction of iodic acid to free iodine cannot take place, and a source of error may thus be introduced into the test. This may be obviated by shaking up one or two c.c. of normal urine with two c.c. of 10 per cent. iodic acid and three c.c. of chloroform. The chloroform is thus colored violet, and then 10 c.c. of the suspected urine are well shaken with the mixture; if diacetic acid is present the chloroform will be decolorized. The author also describes a diazo reaction for the purpose of identifying diacetic acid with absolute certainty, but the procedure is rather complicated and cannot be described in a few words.

Test Breakfast or Test Dinner.—Dörner discusses the subject of whether it is better for routine use to employ the test breakfast or the test dinner, and states that in his experience the results obtained in examining patients by means of the test dinner were much at variance with those obtained by the physicians who sent them for diagnosis and who had based their own observations on determinations made by means of the test breakfast. The author made parallel observations on twelve patients whose stomach contents were analyzed on successive days after each type of test meal. The results showed considerable discrepancy, the amount of free HCl being in every case much less after the larger meal. Dörner therefore, concludes that in making determinations of gastric efficiency, it is better not to rely on the test breakfast alone. The test dinner should also be employed, as it alone furnishes an idea of whether the gastric secretion is sufficient in amount to fulfill the demands made by an ordinary meal. If it is found that the stomach can dispose of the test dinner, it may be assumed that it would be equally efficient in regard to the test breakfast, and the latter need not be resorted to, but if the examination after the test dinner shows a deficiency in free HCl the test breakfast must be employed in order to determine more nearly the degree of incapacity. If only the one test is to be used, it is preferable to give the test dinner. Only in achylia gastrica is more definite information afforded by the test breakfast.

French and Italian Journals.

Professional Dermatoses.—Lévi-Sirugue, after an interesting review of this subject, states that if it is impossible to suppress such dermatoses completely, it is at least possible to diminish the intensity and the repetition of the eruptions by wise prophylaxis. Extreme care will render less dangerous the contact with harmful substances which are met with in the industrial arts. Workmen should bathe frequently, and opportunities for such care should be afforded them free of charge in their places of work. In the summer, perspiration necessitates frequent ablutions. In the winter, cracks in the skin and excoriations which offer a portal of entry to infections should be combated by the application of neutral glycerin. Workkmen should be carefully selected, those showing any predisposition to dermatitis being rejected. Alcoholism predisposes to dermatitis or tends to exaggerate it. The urine of these men should be examined for both sugar and albumin. Rubber gloves offer a protection. Every professional dermatosis should be treated in the beginning, and may then be cured comparatively early. Oxide of zinc is excellent for simple erythema. For pruriginous and bloody lesions, wet anodyne dressings are indicated; boiled water may be employed for this purpose. If the lesion is intense, weak antiseptics may be used. If the epidermis is macerated, pomades are indicated, or if the lesion is very bloody, powder should be used.—*Gazette des Hôpitaux Civils et Militaires.* February 10, 1906.

Dislocation of the Elbow Outward and Backward; Reduction After Arthrotomy; Recovery.—Kirmisson has recently treated a case of this kind. The patient was a young boy and was not brought to the surgeon till twenty-five days after the accident, thus making recourse to arthrotomy necessary. This operation, which was done by the posterior route, easily allowed the reduction of the dislocation. In order to maintain the reduction, the arm was placed in complete extension for some days, and was not put into demiflexion until later. At this time, three months after the operation, the result is excellent. The articulation has recovered all of its movements, extension being the only one which is not yet quite perfect.—*La Presse Médicale* February 3, 1906.

Book Reviews.

The Signs of Internal Disease, with a Brief Consideration of the Principal Symptoms Thereof. By Pearce Kintzing, B.Sc., M.D., Professor of Physical Diagnosis and Diseases of the Heart, Maryland Medical College; Physician to the Franklin Square Hospital, Baltimore, Md., etc. Chicago: The Cleveland Press, 1906.

This is a book containing in a condensed form much information for the student, and a few suggestions which the practitioner will consider valuable. An outgrowth of lectures, as the author says in his preface, it is necessarily rather elementary, and many subjects receive but slight attention, yet it has a distinct value and fulfills the purpose for which it was written better than the majority of publications of the day. The general practitioner of experience will find little that is new, and a very evident lack of detail, but for the beginner it will prove a valuable guide. The chapter on medical anatomy, as far as it goes, is excellent, and the advice to cultivate methodical habits in all attempts at diagnosis will, if followed, be of inestimable value to the student. Some of the important, but rarer diseases, as, for instance, cancer of the stomach, are treated rather slightingly, but in the main the principal points in diagnosis are explained in a clear and concise manner which will make the study of the little book a pleasure. The illustrations are good and the schematic diagrams have the unusual merit of simplicity, which compels instant recognition of their meaning. It is very well edited and indexed.

A Handbook of Climatic Treatment, Including Balneology. By William R. Huggard, M.A., M.D., F.R.C.P., Lond.; H. B. M. Consul at Davos, Switzerland. London: Macmillan & Co., Ltd.; New York: The Macmillan Company, 1906.

This is a somewhat prolix addition to our bibliography on the subject, and like so many other works on climatology, it possesses some excellent features, though little that is really original, and in this respect is disappointing. The author has arranged his work in five parts. Part I. is taken up with a somewhat elementary discussion of meteorology and physics. It is not too technical and is very readable, and in this particular is adapted to the requirements of the medical practitioner. Part II. is devoted to the physiological action of the various meteorological factors. The text is wordy and tedious, and not infrequently the author wanders from the point. Part III. takes up more specifically the various types of climate, which the author has rather ingeniously classified on a new principle of division, namely, the demand made by climate for the production of heat in the organism. There are excellent chapters in this part on Egypt, South Africa, Algiers, Madeira, and the Canary Islands, the Mediterranean, and the British Isles. The chapter on the climatology of the United States is very disappointing. California is excellently handled, but many of the more generally recognized climatic stations in the United States and Canada are not even mentioned. Part IV. is devoted to the subject of balneology, including brief chapters on the "whey cure" and the "grape cure." The concluding Part V., on therapeutics of climate is of very practical interest and value to the physician, and comprises the most interesting chapters of the work.

The Pathology of the Eye. By J. Herbert Parsons, B.S., D.S., Lond., F.R.C.S., Eng.; Assistant Ophthalmic Surgeon, University College Hospital; Assistant Surgeon, Royal London (Moorfields) Ophthalmic Hospital; Ophthalmic Surgeon, Hospital for Sick Children, Great Ormond Street. Vol. II. Histology.—Part II. New York, G. P. Putnam's Sons; London: Hodder & Stoughton, 1905.

The second volume of Mr. Parson' work is one of 381 pages. It is well printed and is abundantly illustrated by 279 figures in the text. Many of the illustrations are from photographs. Almost all are excellent, and bear evidence of having been selected with proper discrimination. Chapter VII. (the first chapter in this volume) of the complete work treats of the histology of the crystalline lens in the normal and in pathological conditions. Chapters of a similar nature on the choroid, retina, optic nerve, orbit, and lacrymal apparatus follow in the order named. This volume, like the first, gives a most excellent presentation of the subject. A thorough knowledge by the author of the work of all investigators in this field is manifest, the evidence obtained is carefully weighed, and what appears to be a just interpretation of the conditions considered is given in language that is direct and can be easily understood. Theories are not discussed at length, but are mentioned either as agreeing with or opposed to the known facts. The impartial, judicial style of the presentation is commendable. The reader may be confident that the statements contained in the volume are based on facts that warrant the position taken. A bibliography of the important writings on each subject is given at the end of the text on that subject. The cytological changes that take place in pathological processes, the study of which is rendered more satisfactory and productive by modern technique, are given proper consideration. The promise of excellence which the first volume implied is fulfilled in the second volume, and will undoubtedly be realized in those to follow. The work cannot fail to be of great value to all who are engaged in the study and practice of ophthalmology. It should be in every medical library.

Skiascopy and Its Practical Application to the Study of Refraction. By Edward Jackson, A.M., M.D., Professor of Ophthalmology in the University of Colorado; Ophthalmologist to the Denver County Hospital; Consultant in Ophthalmology to St. Anthony's Hospital and the Mercy Hospital, Denver. Fourth Edition, Revised and Enlarged. With 28 Illustrations. Denver: The Herrick Book and Stationery Company, 1905.

Jackson's "Skiascopy," in its fourth edition, except in the addition of a chapter entitled "Exact Skiascopy," presents but little change over the volume that preceded it. The excellence of the work is conceded by all ophthalmologists. The subject is presented so simply that the ideas of the author can be grasped by the tyro in ophthalmology, and it is treated so thoroughly that the mastery of the contents of the volume cannot fail to give the student a perfect working knowledge of the art. This work deserves and cannot fail to be in great demand by those who take up the study of skiascopy for the correction of errors of refraction.

The Practice of Medicine, A Text-Book for Practitioners and Students. With Special Reference to Diagnosis and Treatment. By James Tyson, M.D., Professor of Medicine in the University of Pennsylvania, and Physician to the Hospital of the University, etc. Fourth Edition, Revised and Enlarged. With 240 Illustrations, Including Colored Plates. Philadelphia: P. Blakiston's Son & Co., 1906.

Dr. Tyson's admirable book well deserves the popularity that seems to have come to it, and we are pleased to note the appearance of this new edition. Its most conspicuous additions appear to be in the section on animal parasites, which now, by virtue of the new text and many fresh illustrations, is extremely full. The revision of the text as a whole has not in all cases been as thorough as might be desirable, however. For example, in a volume bearing the imprint of the year 1906 one does not expect to see such a statement as that occurring on page 202, to the effect that the latest putative syphilis organism "is that described by Lustgarten in 1884"; or that on page 396, enumerating five special treatises on appendicitis said to be of great value, the latest one of these being dated 1896. The attention of the proofreader is also urgently required in many places, such for example as in the legends on the plate purporting to depict the blood picture of leukemia, and on page 84, regarding the name of the yellow fever mosquito. These are only minor blemishes, however, and do not materially impair the value of what is a well-written and authoritative text-book.

Urinary Analysis and Diagnosis by Microscopical and Chemical Examination. By Louis Heitzmann, M.D., New York. With One Hundred and Thirty-One Illustrations, Mostly Original. New York: William Wood and Company, 1906.

The author of this work is of the opinion that the modern tendency is to lay undue stress on the chemical examination of the urine, at the expense, to some degree, of its microscopical study. In the present volume we accordingly find but sixty-odd pages devoted to the former means of investigation, while the remainder of the book is devoted to an extremely careful and painstaking description of the various structures encountered in urinary sediments. The illustrations are very numerous and show many objects not often depicted in works on the subject, so that the book will rarely be found wanting when it is consulted for the purpose of identifying some one of the unusual elements of the sediment that occasionally puzzle even an experienced microscopist. The volume is well adapted to stimulate thought, and its perusal is recommended to all advanced students. We fancy, however, that most of the modern clinical pathologists would feel inclined to break a lance with the author in regard to his chapter on the differentiation of the epithelial cells occurring in urine under various conditions and the identification of their source, concerning which he says that it "is not at all difficult." The entire subject is one too often neglected, and it is a pleasure to call the attention of the practitioner to a treatise that should prove of the greatest assistance to him in his everyday work.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

Regular Meeting, Held February 15, 1906.

DR. CHARLES L. DANA IN THE CHAIR.

A Statistical Study of Visceral Arteriosclerosis.—Dr. HARLOW BROOKS said that he had included in his study all such arterial changes as had, through disease of the arterial walls, caused a lack of orientation, that was a lack of proper functional relationship between the arteries and their dependent tissues. His series comprised 400 consecutive cases of arterial disease as they had appeared in his personal necroscopical service. He excluded from his analysis all those in which microscopical alterations alone were manifest. The inefficiency of present methods of diagnosis of arterial disease were especially manifested in cases where the lesions were largely or entirely limited to the internal viscera. Of the 400 cases only 154 were capable of diagnosis by present methods. Eight out of the 400 cases presented quite marked alterations in the peripheral vessels without disease of the aorta, or large trunks of the important internal viscera. Of the 400 cases, 368 showed serious disease of the visceral trunks and in 67 of these the visceral changes were associated with disease of the aorta. The occupation was determined in 311 cases. There were 118 laborers, including firemen and blacksmiths, 79 houseworkers, 45 tradesmen, including carpenters, jewelers, etc. Lead workers, painters, and tobacco workers appeared in a separate class. The commonly accepted ideas regarding arterial disease and occupation were substantiated by these figures. In regard to etiology: of the 368 cases of disease of the visceral arteries alcohol could be classed as a possible etiological factor in 149 instances. Nephritis appeared to be the chief cause in 51 cases, syphilis and old age in 38 cases each, and tuberculous disease in 31 cases. The relative involvement of the visceral trunks was about equal in both sexes. In all but 30 of the 368 cases more than a single visceral distribution was affected. Disease of the coronary arteries predominated in point of frequency, though it was often in relatively lesser degree than certain other distributions. Alcohol seemed to be the sole agent in the production of coronary disease in 107 cases. Syphilis was found connected in but 27 instances, and in 10 of these alcohol also appeared. Tuberculosis was found in 19 cases, senility in 15, and excessive use of tobacco in 9. In old age universal involvement of the visceral arteries was the rule. The arteries of the brain were affected in 132 cases and alcohol appeared as the most prominent agent. The renal vessels appeared third in rate of occurrence; they were found markedly involved in 81 cases. Fourth in number were the vessels of the pancreas, which were involved in 74 cases, alcohol still leading as the etiological factor. The hepatic vessels were found diseased in 43 cases, the splenic arteries in 35 cases, and lastly the vessels of the lungs in 20 cases. The celiac axis and its visceral branches were diseased to a greater degree than the other trunks of corresponding size in 19 cases. In regard to the cause of arterial sclerosis it seemed from his study that the changes were likely to appear first, and to be found in greatest degree, in those arterial distributions which were called upon to functionate most actively under the special stimulus at work. After describing the pathological anatomy of this condition, he said that the symptoms which resulted from these alterations were first depressed function, manifested, for instance in the heart, by deficient or irregular muscular contraction, in the pancreas by insufficient production of its digestive ferment, and in the brain by faulty action of the nerve cells or delayed transmission of nerve impulses. By no means all portions of an organ were equally affected. Pain was more or less a constant symptom of visceral arteriosclerosis, the darting or burning agony of angina pectoris being the most familiar example of the symptom. Pain of the same character but of little less severity appeared in other viscera similarly diseased. It had long been recognized that the arteriosclerotic kidney was responsible in a large percentage of cases for a considerable elevation of blood pressure. The rise in blood pressure was not constant but intermittent in the developing stages of the disease. He thought that he had been able to show a definite relationship between this sign and vascular disease of organs other than the kidney, but as yet sufficient post-mortem evidence had not been collected in conjunction with these clinical observations to render them of more than probable value. Most clinicians depended too much on the condition of the peripheral arteries, which he had shown to be diseased in only a relatively small number of cases in which visceral arterial disease, even of pronounced degree, existed. The presence of diminished visceral function with occasional and otherwise unaccountable elevations of blood pressure, should, particularly in connection with possible etiological factors, lead to a suspicion of some localized if not general area of arterial disease. He thought that careful observation of cases of obscure abdominal pain, paroxysmal in character and associated with rise in blood pressure, when sufficiently backed by united clinical and necroscopical evidence, would eventually make it possible to diagnose these generally unrecognizable types of arterial disease while yet in a stage when something could be done for their alleviation and the prevention of their extension.

Dr. EGBERT LE FEVRE said a very important factor brought out was the relation of peripheral arteriosclerosis to that of the viscera. He commended Dr. Brooks' classification of etiological factors, believing they were very important in determining the changes either in the large vessels themselves or in the small vessels subsequent to involvement of the larger ones.

Dr. WILLIAM H. THOMSON thought it was very important and desirable that they should recognize what was the particular factor that led to degeneration and atheroma, and he summed it up in the one word, *strain*. Atheromatous change in any blood-vessel was indicative of some local strain, and this was strikingly illustrated in cases of extreme atheroma not due to systemic causes at all, but only to local ones. He referred to such changes as occurred in varicose veins of the legs, due to some congenital defect of the valves of the veins, similar to the congenital deficiencies which led to inguinal hernia. It was entirely a local condition and not dependent upon blood infection. He said there was another way in which this strain of a column of blood in the vessels led directly to a thickening of its walls, then to marked atheromatous changes, and finally to calcification as well, and that was through the influence of an excess of adrenalin in the blood. Instead of atheromatous changes with thickening of the lumen of the vessel, etc., causing a high tension pulse, he said we should place the effect before the cause; in the majority of instances atheroma resulted from the high tension and not the high tension from the atheroma.

Dr. A. JACOBI said that he now thought it possible to make a positive diagnosis of atheromatous degeneration of the visceral arteries. When one found a heart in a doubtful case that was of fairly normal size, with a great deal of impulse in the small arteries, the probabilities were that there was so much resistance in the peripheral arteries that the heart had to undergo unusual labor; that was met with a strong systolic impulse. In chronic myocarditis the heart might be of normal size or undersized; myocardial changes, when present, were usually complicated with arteriosclerosis of the small arteries. A little exercise, like going upstairs, would cause the development of a murmur, sometimes a strong murmur. Then we were dealing with an incompetent heart muscle. Proper regard for the heart muscle would aid greatly in the proper diagnosis of the condition.

Dr. LEONARD WEBER said that many now recognized that arteriosclerosis was more often a local than a general dis-

ease, and this fact was very important, so far as the therapy was concerned.

The Diagnostic Significance of High Arterial Pressure.—Dr Theodore C. Janeway read this paper. He asked indulgence for a study wholly clinical and subject to the limitations which hedged about all observations upon the living patient. Patients exhibiting persistent high blood pressure as the salient feature of their disordered physiology seemed to be more common in private practice than in hospitals. With a twelve-cm. armlet he thought there could be little question that, under conditions of physical and mental rest, the upper limit of normal systolic pressure—the pressure necessary to obliterate the pulse wave in the brachial artery—might be taken as 145 mm., the lower limit 100 mm. It was wise, in dealing with new patients, to consider no pressure below 166 mm. pathological. This statement was made from recorded figures in over ninety persons who were normal or with indifferent complaints, besides a large number of unrecorded observations. With advancing years the blood pressure tended toward the higher normal figures. While it might be hard to draw the line between gradually developing pathological hypertension and the normal increase of age, one was inclined to consider 160 mm. definitely pathological, when excitement and other hypertensive influences were excluded. The diastolic pressure varied less than the systolic, being, as a rule, between 75 and 110 mm. Almost all physiological and pathological elevations of blood pressure affected the systolic more than the diastolic pressure. The difference between these two measures gave the pressure variation of the pulse which was named by Erlanger the "pulse wave." An apparent hypertension might be confused with a real elevation of mean blood pressure. By apparent hypertension he meant an abnormally high systolic with normal or subnormal diastolic pressure, and, therefore, an only slightly increased mean pressure. This occurred in all cases of marked aortic insufficiency. It afforded an excellent measure of the mechanical effect of the lesion. With an abnormally low pulse the same state of affairs existed. It should be emphasized that where aortic insufficiency or marked bradycardia existed no systolic pressure under 200 mm. should be considered evidence of real hypertension. Marked and lasting elevation of the general level of blood pressure in any individual was an important disturbance of his normal circulatory physiology. Its significance was twofold: first, as evidence of preexisting disease affecting the cardiovascular mechanism; second, as in itself introducing an abnormal factor which must produce secondary changes in the heart and blood-vessels. While real hypertension was more common in chronic nephritis than in any other condition, cardiac hypertrophy was occasionally seen at autopsy without either chronic nephritis or a valvular lesion to account for it clinically, it was difficult for him to admit a chronic nephritis as proved when repeated examinations showed urine quantitatively and qualitatively normal. In studying this question during the past two years the number of patients in whom pressures between 100 and 200 mm. were found was so large that time did not suffice for a careful scrutiny of all the histories, but it was evident that many persons showed these lesser degrees of hypertension in whom kidney disease could be fairly excluded; though many others were clearly cases of chronic nephritis. In 130 cases in which the systolic pressure reached 200 mm. he had tabulated the findings. He had given the diagnosis of nephritis the benefit of the doubt where there was any possible excuse for it. Of these 130 cases, 81 per cent. had chronic nephritis, 6 per cent. were doubtful, and there was no evidence of nephritis in 13 per cent. The figures obtained demonstrated conclusively the value of hypertension as evidence of chronic nephritis on the positive side, but they also showed that there was a group of patients, 10 to 15 per cent. of the whole number, in whom extremely high blood-pressure with cardiac hypertrophy, arterial changes, and quite the same clinical picture existed independently of Bright's disease. If the high blood-pressure was due to obliterating endarteritis of the small arteries, the splanchnics especially, then we must assume some individual immunity of the renal vessels in these cases, or a relative immunity. If our theory be that of vasoconstrictor spasm of toxic origin, then there must have been several poisons, differing in their effects upon the kidneys, or a greater individual resistance of the latter. What seemed to him important was to hold clearly in mind the physiological picture of chronic arterial hypertension as a type of cardiovascular disease, usually secondary to chronic Bright's but at times associated with it. From this hypertension might arise many dangers, as cerebral hemorrhage, or gradually developing ventricular asystole. His personal experience and that of most others who had compared their tactile impressions with routine blood pressure determinations was not complimentary to the *tactus eruditus*. Even pressures over 200 mm. might fail to be appreciated where the pulse was small or the artery deeply placed. Hypertrophy of the left ventricle and accentuation of the aortic second sound were also often difficult of detection. He had found in his series of 130 cases that 10 per cent. showed absolutely no evidence of cardiovascular disease except the blood-pressure, reading, in a number of cases because obesity made examination of the heart almost hopeless. In four cases there was no enlargement of the heart, but some lifting impulse or accentuation of the aortic second sound; and in 16 other cases there was evidence of very slight hypertrophy, which might have easily escaped any but an expert in physical diagnosis. In all, one-quarter of the cases would have been recognized with difficulty or not at all without the sphygmomanometer, except on critical examination by a skilled observer. To those who felt the poverty of our diagnostic resources the accurate measurement of blood-pressure must prove a valuable addition to our methods of physical examination, but to those who had not acquired the habit of painstaking observation and careful weighing of evidence the little knowledge which the instrument could yield might, like other bits of laboratory diagnosis, prove a dangerous thing.

Dr. Egbert Le Fevre said that high blood-pressure was recognized with instruments of precision and it had been shown that the *tactus eruditus* was not always correct. In the hospital they had for a long time tested themselves on this point, endeavoring to estimate the blood-pressure with the sense of touch and then determining the correctness of their diagnosis by the use of Janeway's instrument. Very seldom was the instrument confirmatory of what was determined by the touch. The relation of high arterial tension to chronic nephritis was interesting and one was not always correct in saying that in cases with high arterial tension, 200 or over, when the urine was of low specific gravity, with occasional casts and some albumin, the high tension was due to the kidney condition alone. Just what the conditions were which caused a persistent high tension was still a mystery without autopsy. The secretion of the suprarenal glands might cause it.

Medical Education in Japan.—Baron Kanehiro Takaki, M.D., F.R.C.S., F.R.C.P., of Tokio, Surgeon-General (Reserve) of the Japanese Navy, addressed the members of the Academy on medical education in Japan. He said he had been educating a number of medical students for more than twenty-five years, both in connection with the naval medical school and also in private medical schools. When he was a junior officer in the navy it was insisted upon that they should have a special school for the education of the naval medical officers. This was provided for. This school was started in 1872, and since then they had educated sixteen men. When those sixteen men were graduated he was away from the country. The officers of the medical bureau thought they would be able to go on without special education, and when he returned he found that those who had been educated outside the medical

school could not understand any foreign language; at the same time, their practical knowledge was quite insufficient. These medical officers must go on board ship, must visit the various ports of foreign countries, in order to determine the presence or absence of dangerous diseases. They were also called upon to go ashore to find out if epidemics were present. None of these things could they do, because they did not understand foreign languages. Therefore Baron Takaki urged the reestablishment of the medical school, and as a result they had to educate eighty medical officers, making ninety-six altogether, and these were the chief acting members of the medical department of the Japanese Navy. Among the first sixteen graduated was Surgeon-General S. Suzuki; also the president of the present medical bureau and the chief surgeon of the naval stations. It was in order to advance the sanitation of the navy that these ninety-six men had been educated. He regretted to state that since he had left the navy this medical school had been abolished again. He believed the army and navy should have a special medical school for the education of their medical officers. The officers of the army and navy received their education in certain schools from the beginning, *i.e.* the youth or boy underwent discipline that gave him an especial character, different from those who were brought up in the ordinary schools. These men were inclined to look down upon the medical officers. In the near future, he believed, they would have special schools for the education of the medical officers of both the army and navy. The medical officers must receive more recognition than they had before, and they deserved to have it. In the time of war between Japan and China the director of the medical bureau of both the army and navy had rank equal to the line officers or major-general. The Baron said he had been trying to educate the common medical men, and he started twenty-five years ago in this on a small scale. He had always felt that they should use the English language, and he intended keeping up his English, and, at the same time, educate his medical men to speak it. Up to three years ago any medical student could enter the school who had a certain knowledge of preliminary subjects; but since then there was a new regulation adopted, so that now no medical student could enter unless he first passed an examination in English. To-day there were 407 students, of whom 350 had studied English. The Baron here told what branches they studied at different periods of their college life. Every boy in Japan must go to school After ten years they entered the higher primary school; then they went to the middle school; after graduating from this they entered a higher school, which was said to have no equivalent in Europe or America. Here they received their higher education. At the end of three years they went to the university. They had in Japan three medical universities, having each a four-year course. When the student finished the middle school he could enter here and complete his course in four years' time. After completing their medical studies, many of the Japanese went to Germany; Japanese medical education resembled very closely that of Germany. The Baron's own son studied English, then French, and was at present traveling in Australia, getting along very well without a guide. He also studied German and intended to study two or three other languages in Vienna. As to the recognition of the medical service in his country, up to twenty-five years ago not much was given them, and they saw that, in order to gain recognition, something must be done; they then thought it would be best to educate the people, telling them how to take care of themselves. Therefore, in Tokio in 1883, there was started the Japan Hygienic Society, which met twice a month. This was the beginning. Then every district and province formed its own branch of the society, meeting once or twice a month. This had been undertaken entirely by the medical men. At last the public came to understand that the medical men must be respected Now they recognized how important the medical service was to the country. The art of physic and surgery had been raised in both the army and navy. If the public would recognize the importance of the medical science directed towards the preservation of life and not merely directed to the treatment of the sick and wounded, he thought much would be accomplished. In the future medical science should be used largely for the prevention of disease, not merely the treatment of existing disease.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON OBSTETRICS AND GYNECOLOGY.

Stated Meeting, Held January 25, 1906.

DR. CHAS. F. ADAMS IN THE CHAIR.

Election of Officers.—*Chairman*, Dr. Arnold Sturmdorf; *Secretary*, Dr. Howard C. Taylor.

Specimen of Tubal Pregnancy.—Dr. LEONARD S. RAU presented this specimen which was removed from a woman, twenty-three years old, married four years and who had had, three years previous, a premature delivery. Since this time she had been regular in her menstruation. Four days before she was admitted to the hospital she was suddenly taken with severe pain in the left side, which lasted for hours before subsiding. The pain returned later and a slight bleeding appeared from the vagina. A diagnosis was made of ectopic gestation and she was sent to the hospital. When Dr. Rau first saw her he was able to feel a distinct mass on the left side. The uterus was moderately enlarged. The abdomen was opened and the specimen presented removed. The tube was filled with large organized blood clots and was not ruptured, but so nearly ruptured that in taking it out it was torn at one point. There was also a small parovarian cyst as well as cyst of the ovary itself. There was to be seen a well-formed corpus luteum. An uneventful recovery followed. The pathologist reported that the ovary showed typical luteal cells; diagnosis, corpus luteum (verum). The embryo showed embryonic cells disorganized and of the epithelial type. There were well-organized blood clots and placental cells. A diagnosis was made of embyro in the early stages, under two months.

Dr. EGBERT H. GRANDIN took exception to the title of the case as found upon the announcement card, "unruptured tubal abortion." He said there was a marked distinction between a ruptured tube which was a true ectopic gestation and a tubal abortion. He congratulated Dr. Rau upon making such a diagnosis and said that many years ago a number of men had questioned if such a diagnosis could be made. Four years ago he made a diagnosis of unruptured (not tubal) abortion in his office in a single woman, and he operated within twenty-four hours and confirmed his diagnosis. Last August the same woman came to him and he made the diagnosis of ectopic gestation unruptured (not a tubal abortion). He operated and established his diagnosis. There was a vast difference between tubal abortion, unruptured ectopic, and ruptured ectopic gestation. He further said that those men who were trained in the symptomatology of such cases should remember that the symptoms were not as a rule as laid down in the text-books, and also that women should not be considered to be, like Cæsar's wife, above suspicion, but always under suspicion.

Dr. S. MARX said that it was uniformly admitted that tubal abortion meant only one thing and one thing only, *i.e.* the extrusion of the fetus through the fimbriated extremity of the tube into the abdominal cavity. In tubal rupture there was a break in the continuity of the tube.

Dr. ARNOLD STURMDORF said that if the fetus was dead and surrounded by blood clots some authorities considered this to be a tubal abortion.

Dr. SIDNEY D. JACOBSON said that the nomenclature of this subject under discussion needed revising. As a matter of fact there was no such thing as a ruptured tubal preg-

nancy, because the tube did not rupture. A histological examination of the tube showed that the cells surrounding the ovum had eaten away the mucosa muscularis, eaten through the substance of the wall of the tube. He believed the term "ruptured tubal pregnancy" must sooner or later become obselete.
